| Field | Description                                                                                                                                                                                                                                                                                                                                                                                                                               |
|-------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|       | TC_LCFTCBn indicates the number of commands which have been completely transferred from CFIFOx when a current command transfer from CFIFOx to CBuffern is initiated. TC_LCFTCBn is a copy of the corresponding TC_CFx in <a href="#">EQADC CFIFO Transfer Counter Register 0 (EQADC_CFTCR0)</a> , captured at the time a current command transfer from CFIFOx to CBuffern is initiated. This field has no meaning when LCFTCBn is 0b1111. |

**29.5.17 EQADC CFIFO Status Snapshot Register 1 (EQADC\_CFSSR1)**

The EQADC CFIFO Status Snapshot Registers (EQADC\_CFSSR) contain status fields to track the operation status of each CFIFO and the transfer counter of the last CFIFO to initiate a command transfer to the internal CBuffers. EQADC\_CFSSR0-1 are related to the on-chip CBuffers (CBuffer0-1). All fields of a particular EQADC\_CFSSR register are captured at the beginning of a command transfer to the CBuffer associated with that register. Note that captured status register values are associated with previous command transfer. This means that the CFSSR registers capture the status registers before the status registers change because of the transfer of the current command that is about to be popped from the CFIFO. The EQADC\_CFSSR registers are read only. Writing to the EQADC\_CFSSR registers has no effect.

Address: 0h base + A4h offset = A4h

### 29.5.18 EQADC CFIFO Status Register (EQADC\_CFSR)

The EQADC CFIFO Status Register (EQADC\_CFSR) contains the current CFIFO status. The EQADC\_CFSR registers is read only. Writing to the EQADC\_CFSR register has no effect.

**Table 29-42. Current CFIFO Status**

| CFIFO Status        | Field Value | Explanation                                                                                                                                                                                                                                                                                                                                                  |
|---------------------|-------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

**29.5.20 EQADC CFIFO0 Register (EQADC\_CF0Rn)**

The EQADC CFIFO Registers (EQADC\_CFxRw) (x=0, .., 5; w=0, .., 3) provide visibility of the contents of a CFIFO for debugging purposes. Each CFIFO has four registers which are uniquely mapped to its four 32-bit entries. See [EQADC command FIFOs](#) for more information on CFIFOs. These registers are read only. Data written to these registers is ignored.

| 16–31<br>RFIFO5_DATAW | RFIFO5 Data w (w = 0, ..., 3)<br>Reading RFIFOx_DATAw returns the value stored on the wth entry of RFIFOx. Each RFIFO is composed of four 16-bit entries, with register 0 being mapped to the one with the smallest memory mapped address. |

**29.5.33 On-chip ADC registers**

This section describes a list of registers that control on-chip ADC operation. The ADC registers are not part of the CPU accessible memory map. These registers can only be accessed indirectly through configuration commands. There are non memory mapped registers that are individual per ADC, plus other registers that are shared by both ADCs. The address, usage, and access privilege of each register is shown in [Table 29-110](#). Data written to or read from reserved areas of the memory map is undefined.

Their assigned addresses are the values used to set the ADC\_REG\_ADDRESS field of the read/write configurations commands bound for the on-chip ADCs. These are half-word addresses. Further, the following restrictions apply when accessing these registers:

- Registers ADC0\_CR, ADC0\_GCCR, ADC0\_OCCR, ADC0\_AGR1/2 and ADC0\_AOR1/2 can only be accessed by configuration commands sent to CBuffer0.
- Registers ADC1\_CR, ADC1\_GCCR, ADC1\_OCCR, ADC1\_AGR1/2 and ADC1\_AOR1/2 can only be accessed by configuration commands sent to CBuffer1.
- Registers ADC\_TSCR, ADC\_TBCR, ADC\_ACR1-14, ADC\_EACR1-14 and ADC\_PUDCR0-7 can be accessed by configuration commands sent to CBuffer0 or to CBuffer1. A data write to any of these registers through a configuration command sent to CBuffer0 will write the same memory location as when writing to it through a configuration command sent to CBuffer1.

### Note

Simultaneous write accesses from CBuffer0 and CBuffer1 to any of the shared registers are not allowed.

**Table 29-110. On-Chip ADC Memory Map**

| ADC address | Use                                                                                                                                                  | Access     |
|-------------|------------------------------------------------------------------------------------------------------------------------------------------------------|------------|
| 0x00        | ADC0/ADC1 <sup>1</sup> Conversion Command for Standard Configuration (See <a href="#">Conversion command format for the standard configuration</a> ) | Write      |
| 0x01        | ADC0/ADC1 Configuration Control Register (ADC0_CR, ADC1_CR)                                                                                          | Write/Read |
| 0x02        | Time Stamp Control Register (ADC_TSCR)                                                                                                               | Write/Read |
| 0x03        | Time Base Counter Register (ADC_TBCR)                                                                                                                | Write/Read |
| 0x04        | ADC0/ADC1 Gain Calibration Constant Register (ADC0_GCCR, ADC1_GCCR)                                                                                  | Write/Read |
| 0x05        | ADC0/ADC1 Offset Calibration Constant Register (ADC0_OCCR, ADC1_OCCR)                                                                                | Write/Read |
| 0x06- 0x07  | Reserved                                                                                                                                             | -          |
| 0x08        | ADC0/ADC1 Conversion Command for Alternate Configuration 1 (See <a href="#">Conversion command format for alternate configurations</a> )             | Write      |
| 0x09        | ADC0/ADC1 Conversion Command for Alternate Configuration 2 (See <a href="#">Conversion command format for alternate configurations</a> )             | Write      |
| 0x0A        | ADC0/ADC1 Conversion Command for Alternate Configuration 3 (See <a href="#">Conversion command format for alternate configurations</a> )             | Write      |
| 0x0B        | ADC0/ADC1 Conversion Command for Alternate Configuration 4 (See <a href="#">Conversion command format for alternate configurations</a> )             | Write      |
| 0x0C        | ADC0/ADC1 Conversion Command for Alternate Configuration 5 (See <a href="#">Conversion command format for alternate configurations</a> )             | Write      |
| 0x0D        | ADC0/ADC1 Conversion Command for Alternate Configuration 6 (See <a href="#">Conversion command format for alternate configurations</a> )             | Write      |

| 0xA2-0xFE   | Reserved                                                                       | -          |
| 0xFF        | Reserved for dummy write command <sup>3</sup>                                  | Write      |

1. Throughout the table, ADC0/ADC1 indicates that if the command is stored in CBuffer0 it will be applied to ADC0 and if in CBuffer1 it applies to ADC1. If this indication is omitted the register applies for both ADC0 and ADC1, independent of the CBuffer used.
2. See the chip-specific EQADC information for details about which analog inputs have pull up/pull down control
3. Defined as an address for dummy write operation. Read is not allowed.

### 29.5.33.1 ADC0/1 Control Registers (ADC0\_CR and ADC1\_CR)

The ADC0/1 Control Registers (ADC0/1\_CR) is used to define the standard configuration of the ADC. In the standard configuration, the parameters contained in the Alternate Configuration Control Registers (ADC\_ACR1-14) are fixed at their reset value. A conversion uses the standard configuration when the conversion command (with the standard format) is written to address 0x00 of the on-chip ADC memory map. Refer to [Conversion command format for the standard configuration](#).

## Memory map and register definition

ADC0 Register address: 0x01

|        | 0       | 1 | 2 | 3 | 4         | 5 | 6          | 7           | 8            | 9            | 10          | 11 | 12 | 13 | 14 | 15 |

| Field              | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
|--------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                    | <p>The ADC0/1_TBSEL[0:1] field selects the time information to be used as timestamp according to <a href="#">Table 29-112</a>.</p> <p><b>Note:</b> This selection is overridden by the corresponding field ATBSEL in the ADC_ACR1-14 registers when the alternate conversion command is used.</p>                                                                                                                                                                                                                                                                                                                                                                   |
| ADC0/1_ODD_PS      | <p>Clock Prescaler Odd Rates Selector for ADC0/1</p> <p>The ADC0/1_CLK_DTY field controls the duty rate of the ADC0/1 clock when the ADC0/1_CLK_PS field is asserted. The generated clock has an odd number of system clock cycles, therefore this field is used to select a clock duty higher or lower than 50%.</p> <p>0 Even divide factor is selected. The final divide factor is dependent of ADC0/1_CLK_PS field.</p> <p>1 Odd divide factor is selected. The final divide factor is dependent of ADC0/1_CLK_PS field.</p>                                                                                                                                    |
| ADC0/1_CLK_DTY     | <p>Clock Duty Rate Selector for ADC0/1 (for odd divide factors)</p> <p>The ADC0/1_ODD_PS field is used together with the ADC0/1_CLK_PS field to define even/odd divide factors in the generation of the ADC0/1 clocks. See <a href="#">Table 29-113</a> for available divide factors.</p> <p>0 clock low interval is longer 1 clock cycle than high pulse.</p> <p>1 clock high pulse is longer 1 clock cycle than low portion.</p>                                                                                                                                                                                                                                  |
| ADC0/1_CLK_SEL     | <p>Clock Selector for ADC0/1</p> <p>The ADC0/1_CLK_SEL is used to select between the system clock signal or the prescaler output signal. The prescaler provides the system clock signal divided by a even factor from 2 to 64. This is required to permit the ADC to run as fast as possible when the device is in Low Power Active mode and system clock is around 1 MHz.</p> <p><b>Note:</b> The ADC0/1_CLK_SEL bits must only be written when the ADC0/1_EN bit is negated. ADC0/1_CLK_SEL can be set during the same write cycle used to set ADC0/1_EN.</p> <p>0 Prescaler output clock is selected.</p> <p>1 System clock is selected - maximum frequency.</p> |
| ADC0/1_CLK_PS[0:4] | <p>Clock Prescaler Field for ADC0/1</p> <p>The ADC0/1_CLK_PS field controls the system clock divide factor for the ADC0/1 clock as in <a href="#">Table 29-113</a>. See <a href="#">ADC clock and conversion speed</a> for details about how to set ADC0/1_CLK_PS.</p> <p><b>Note:</b> The ADC0/1_CLK_PS field must only be written when the ADC0/1_EN bit is negated. This field can be configured during the same write cycle used to set ADC0/1_EN.</p>                                                                                                                                                                                                          |

**Table 29-112. Timebase selection**

| ADC0/1_TBSEL[0:1] | Definition                                                                          |
|-------------------|-------------------------------------------------------------------------------------|
| 00                | Selects internally generated time base as time stamp.                               |
| 01                | Selects imported time base 1 indicated by SRV1 bit field of EQADC_STACCCR register. |
| 10                | Selects imported time base 2 indicated by SRV2 bit field of EQADC_STACCCR register. |

### 29.5.33.2 ADC Time Stamp Control Register (ADC\_TSCR)

The ADC Time Stamp Control Register (ADC\_TSCR) contains a system clock divide factor used in the making of the time base counter clock. It determines at what frequency the time base counter will run. ADC\_TSCR can be accessed by configuration commands sent to CBuffer0 or to CBuffer1. A data write to ADC\_TSCR through a configuration command sent to CBuffer0 will write the same memory location as when writing to it through a configuration command sent to CBuffer1.

#### Note

Simultaneous write accesses from CBuffer0 and CBuffer1 to ADC\_TSCR are not allowed.

### 29.5.33.3 ADC Time Base Counter Registers (ADC\_TBCR)

The ADC Time Base Counter Register (ADC\_TBCR) contains the current value of the time base counter. ADC\_TBCR can be accessed by configuration commands sent to CBuffer0 or to CBuffer1. A data write to ADC\_TBCR through a configuration command sent to CBuffer0 will write the same memory location as when writing to it through a configuration command sent to CBuffer1.

#### Note

Simultaneous write accesses from CBuffer0 and CBuffer1 to ADC\_TBCR are not allowed.

ADC0/1 Register address: 0x03

**Figure 29-106. ADC Time Base Counter Register (ADC\_TBCR)****Table 29-116. ADC\_TBCR field descriptions**

|-----------------|-------------------------------|
| TBC_VALUE[0:15] | Time Base Counter VALUE Field |

**Table 29-116. ADC\_TBCR field descriptions**

| Field | Description                                                                                                                                                                                                                                                                                      |
|-------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|       | The TBC_VALUE field contains the current value of the time base counter. Reading TBC_VALUE returns the current value of time base counter. Writes to TBC_VALUE register load the written data to the counter. The time base counter counts from 0x0000 to 0xFFFF and wraps when reaching 0xFFFF. |

### 29.5.33.4 ADC0/1 Gain Calibration Constant Registers (ADC0\_GCCR and ADC1\_GCCR)

The ADC0/1 Gain Calibration Constant Register (ADC0/1\_GCCR) contains the gain calibration constant used to fine-tune the ADC0/1 conversion results. See [ADC calibration feature](#) for details about the calibration scheme used in the EQADC.

**ADC0 Register address: 0x04**

|--------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| GCC0/1[0:14] | Gain calibration constant for ADC0/1<br><br>GCC0/1 contains the gain calibration constant used to fine-tune ADC0/1 conversion results. It is a unsigned 15-bit fixed pointed value. The gain calibration constant is an unsigned fixed point number expressed in the GCC_INT.GCC_FRAC binary format. The integer part of the gain constant (GCC_INT) contains a single binary digit while its fractional part (GCC_FRAC) contains fourteen digits. For details about the GCC data format, see <a href="#">MAC unit and operand data format</a> . |

29.5.33.5    **ADC0/1 Offset Calibration Constant Registers  
(ADC0\_OCCR and ADC1\_OCCR)**

The ADC0/1 Offset Calibration Constant Register (ADC0/1\_OCCR) contains the offset calibration constant used to fine-tune of ADC0/1 conversion results. The offset constant is a signed 14-bit integer value. See [ADC calibration feature](#) for details about the calibration scheme used in the EQADC.

**ADC0 Register address: 0x05**

**ADC1 Register address: 0x05**

**Figure 29-108. ADC0/1 Offset Calibration Constant Registers (ADC0/1\_OCCR)**

**Table 29-118. ADC0/1\_OCCR field descriptions**

| Field        | Description                                                                                                                                                                                                              |

29.5.33.6    **Alternate Configuration 1-14 Control Registers  
(ADC\_ACR1-14)**

The Alternate Configuration Control Registers (ADC\_ACR1-14) are used to configure the alternate configurations of the ADC. There are 14 possible alternate configurations, each one associated with one of the ADC\_ACR1-14 registers. All alternate configurations share the same standard configuration parameters from the ADC0/1\_CR

registers, plus additional configuration parameters contained in the ADC\_ACR1-14. A conversion uses one of the alternate configurations when the conversion command (with the alternate configuration format) is written to an address in the range 0x08-0x15 of the on-chip ADC memory map. It also can use the Extended Alternated Configurations as described in [Extended Alternate Configuration 1-14 Control Registers \(ADC\\_EACR1-14\)](#) if bit DAM=1. See [Conversion command format for alternate configurations](#).

**ADC0/1 Register address: 0x30**

**Table 29-119. ADC\_ACR1-14 field descriptions**

| Field     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
|-----------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| RET_INH   | <p>Result Transfer Inhibit / Decimation Filter Pre-Fill</p> <p>This bit is used to inhibit the transfer of the result data from the peripheral module to the result queue. When the module is a Decimation Filter, this bit sets the filter in a special mode (PRE-FILL) in which it does not generate decimated samples out from the conversion results received from the EQADC block, but the conversion samples are used by the filter algorithm. This feature allows a proper initialization of the Decimation Filter without generating any decimated result. Or this bit is useful for sending the result of the ADC to the STAC bus master but not putting the result in the result queue.</p> <p><b>Note:</b> Refer to the block guide of each peripheral module to obtain the correct behavior of the companion module to the PRE-FILL mode.</p> <p>0 Result transfer to result queue / Decimation Filter in filtering mode</p> <p>1 No result transfer to result queue / Decimation Filter PRE-FILL mode</p> |
| DEST[0:3] | Conversion Result Destination Selection                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |

Up to fifteen devices can be connected to the parallel interface, using the DEST field to select which one receives the conversion result.<br><br>The data format is specified by the FMTA bit in the Alternate Configuration Control Register.                                          |

29.5.33.7 ADC0/1 Alternate Gain Registers (ADC0\_AGR1-2 and ADC1\_AGR1-2)

The Alternate Gain Registers (ADC0\_AGRx and ADC1\_AGRx, x=1-2) contain the gain calibration constants used to fine-tune the ADCs conversion results for alternate configurations 1 or 2. A conversion from an ADC uses the corresponding ADC0\_AGRx or ADC1\_AGRx register when the conversion command (with the alternate configuration format) is written to an address in the range 0x08-0x09 of the on-chip ADC memory map. See [ADC calibration feature](#) for details about the calibration scheme used in the EQADC.

ADC0 Register address: 0x31  
ADC0 Register address: 0x35

ADC1 Register address: 0x31  
ADC1 Register address: 0x35

 = Unimplemented or Reserved

| Field            | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| ALTGCC0/1x[0:14] | Alternate Gain Calibration Constant<br><br>ALTGCC0/1x[0:14] contain the gain calibration constants used to fine-tune ADC0/1 conversion results for alternate configurations 1 and 2. The gain calibration constants are 15-bit unsigned fixed point numbers expressed in the <i>GCC_INT.GCC_FRAC</i> binary format. The integer part of the gain constants ( <i>GCC_INT</i> ) contain a single binary digit while their fractional part ( <i>GCC_FRAC</i> ) contain fourteen digits. For details about the GCC data format, see <a href="#">MAC unit and operand data format</a> . |

### 29.5.33.8 ADC0/1 Alternate Offset Register (ADC0\_AOR1-2 and ADC1\_AOR1-2)

The Alternate Offset Registers (ADC0\_AORx and ADC1\_AORx, x=1-2) contain the offset calibration constants used to fine-tune ADCs conversion results for alternate configurations 1 and 2. The offset constants are signed 14-bit integer values. See [ADC calibration feature](#) for details about the calibration scheme used in the EQADC.

ADC0 Register address: 0x32

ADC0 Register address: 0x36

ADC1 Register address: 0x32

ADC1 Register address: 0x36

| ALTOCC0/1x[0:13] | Alternate Offset Calibration Constant<br><br>ALTOCC0/1x[0:13] contain the offset calibration constants used to fine-tune ADCs conversion results for alternate configurations 1 or 2. Negative values should be expressed using the two's complement representation. |

### 29.5.33.9 Extended Alternate Configuration 1-14 Control Registers (ADC\_EACR1-14)

The Extended Alternate Configuration Control Registers (ADC\_EACR1-14) are used together with the Alternate Configuration Control Registers (ADC\_ACR1-14) of the same number to complement the alternate configurations of the ADC. A conversion uses one pair of the alternate configuration regs (normal and extended) when the conversion

command (with the alternate conversion format) is written to an address in the range 0x08-0x15 of the on-chip ADC memory map. See [Conversion command format for alternate configurations](#).

**Table 29-123. ADC\_EACR1-14 field descriptions (continued)**

| Field             | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
|-------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                   | 1 Right justified signed                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| RPSI2             | <p>Return Parallel Side Interface for DEST2</p> <p>The RPSI2 bit is used in the companion module that has two PSI interfaces (PSI0 and PSI1) that are connected to two eQADCs. It specifies in the companion module if the data received from one PSI should be transmitted to the same PSI or to the other one.</p> <p><b>Note:</b> The companion module may take samples from two eQADCs, allowing double sample rate. If the RPSI bits are different, the results are sent to just one of the eQADCs.</p> <p><b>Note:</b> It is not allowed to use RPSI2=1 when the SoC has only one eQADC. It can occur errors in the companion module due to routing error.</p> <p>0 Companion module results from this eQADC are sent back to the same eQADC using the same PSI.</p> <p>1 Companion module results from this eQADC are sent to the other PSI</p> |
| FLEN2             | <p>Flush Enable to DEST2</p> <p>The FLEN2 bit enables the transfer of the flush command given by the FFMT field from the alternate conversion command when DEST&gt;0.</p> <p>0 No flush command is transmitted to DEST2.</p> <p>1 Flush command is sent to DEST2 if specified by FFMT when DEST&gt;0.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| TEN2              | <p>Enable MESSAGE_TAG2 to DEST2</p> <p>This bit specifies if the MESSAGE_TAG2 value should be used to the result transfer of DEST2. See <a href="#">Table 29-124</a> for more details.</p> <p>0 MESSAGE_TAG2 is disabled.</p> <p>1 MESSAGE_TAG2 is enabled.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| MESSAGE_TAG2[0:3] | <p>MESSAGE TAG 2 Field</p> <p>Same as the MESSAGE_TAG field in the Conversion Command as described in <a href="#">Conversion command format for the standard configuration</a>. <a href="#">Table 29-128</a> describes the meaning of the MESSAGE_TAG2.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |

29.6 Functional description

29.6.1 Overview

The EQADC provides a parallel interface to two on-chip ADCs and a parallel side interface to on-chip companion modules, like a decimation filter. The two on-chip ADCs are architected to allow access to all the analog channels.

Initially, command data is contained in system memory in a user defined data structure which is likely to be a queue as depicted in [Figure 29-1<sup>3</sup>](#). Command data is moved between the CQueues and CFIFOs by the host CPU or by the DMAC which respond to interrupt and DMA requests generated by the EQADC. The EQADC supports software and hardware triggers from other blocks or external pins to initiate transfers of commands from the multiple CFIFOs to the on-chip ADCs.

CFIFOs can be configured in single-scan or continuous-scan mode. When a CFIFO is configured in single-scan mode, the EQADC scans the CQueue one time. The EQADC stops transferring commands from the triggered CFIFO after detecting the EOQ bit set in the last transfer. After an EOQ bit is detected, software involvement is required to rearm the CFIFO so that it can detect new trigger events.

When a CFIFO is configured for continuous-scan mode, the whole CQueue is scanned multiple times. After the detection of an asserted EOQ bit in the last command transfer, command transfers can continue or not depending on the mode of operation of the CFIFO.

CFIFO0 has a special configuration option to allow a repetitive sequence of conversion commands (streaming mode) with high priority characteristics (abort operation) or not. This feature is useful with the immediate conversion command feature that allows the immediate execution of a conversion command or a sequence of commands with critical timing even with the possibility of abortion of some current ADC conversion in progress. The aborted command is stored and executed again as soon as the critical timing commands have been finished.

The multiple Result FIFOs (RFIFOs) can receive data from the on-chip ADCs or from on-chip companion modules. Data from the on-chip ADCs can be routed to the side interface, processed by the on-chip companion modules and then routed back through the side interface to the RFIFOs.

## 29.6.2 Data flow in EQADC

### 29.6.2.1 Overview and basic terminology

[Figure 29-115](#) shows how command data flows inside the EQADC system. A Command Message is the predefined format at which command data is stored on the CQueues. A Command message has 32 bits and is composed of two parts: a CFIFO header and an ADC Command. Command messages are moved from the CQueues to the CFIFOs by the

3. Command and result data can be stored in system memory in any user defined data structure. However, in this document it will be assumed that the data structure of choice is a queue, since it is the most likely data structure to be used and because queues are the only type of data structure supported by the DMAC.

host CPU or by the DMAC as they respond to interrupt and DMA requests generated by the EQADC. The EQADC generates these requests whenever a CFIFO is not full. *The FIFO Control Unit* will only transfer to a CBuffer the ADC command part of the Command Message. Information in the CFIFO header together with the upper bit of the ADC command is used by the *FIFO Control Unit* to arbitrate which triggered CFIFO will be transferring the next command.

**Figure 29-115. Command Flow during EQADC operation**

ADC commands sent to the on-chip CBuffers are executed in a first-in-first-out basis with exception when the immediate conversion command function is enabled. Three types of results can be expected: data read from an ADC register, a conversion result, or a time stamp.

### Note

While the EQADC pops commands out from a CFIFO, it also is checking the number of entries in the CFIFO and generating requests to fill it. The process of pushing and popping commands to and from a CFIFO can occur simultaneously. However, this is not true for CFIFO0 when configured to operate in streaming mode for popping.

The *FIFO Control Unit* expects all incoming results to be shaped in a predefined Result Message format. [Figure 29-116](#) shows how result data flows inside the EQADC system. Results generated on the on-chip ADCs are adjusted considering the selected resolution of the ADC and are formatted into result messages inside the *Result Format and Calibration Sub-Block*. This result message can be routed directly to one of the RFIFOs or to an on-chip companion module via the parallel side interface. After the data is processed by the companion module, it can be routed back to one of the RFIFOs via the side interface with the correct format. A result message is composed of an RFIFO header and an ADC Result. The *FIFO Control Unit* decodes the information contained in the RFIFO header to determine the RFIFO to which the ADC result should be sent. Once in an RFIFO, the ADC result is moved to the corresponding RQueue by the host CPU or by the DMAC as they respond to interrupt and DMA requests generated by the EQADC. The EQADC generates these requests whenever an RFIFO has at least one entry.

### Note

While conversion results are returned, the EQADC is checking the number of entries in the RFIFO and generating requests to empty it. The process of pushing and popping ADC results to and from an RFIFO can occur simultaneously.

Figure 29-116. Result Flow during EQADC operation

### 29.6.2.2 Message format in EQADC

This section explains the command and result message formats used for on-chip ADC operation

A Command Message is the predefined format at which command data is stored on the CQueues. A Command message has 32 bits and is composed of two parts: a CFIFO header and an ADC Command. The size of the CFIFO header is fixed to 6 bits, and it works as inputs to the *FIFO Control Unit*. It controls when a CQueue ends, when it pauses. Information contained in the CFIFO header, together with the upper bit of the ADC Command is used by the *FIFO Control Unit* to arbitrate which triggered CFIFO will transfer the next command. ADC commands are encoded inside the least significant 26 bits of the command message.

A Result message is composed of an RFIFO header and an ADC Result. The *FIFO Control Unit* decodes the information contained in the RFIFO header to determine the RFIFO to which the ADC result should be sent. An ADC result is always 16 bits long.

### 29.6.2.2.1 Message Formats for On-Chip ADC Operation

This section describes the Command/Result message formats used for on-chip ADC operation.

#### 29.6.2.2.1.1 Conversion command format for the standard configuration

Figure 29-117 describes the format for conversion commands when interfacing with the on-chip ADCs in the standard configuration. The standard configuration is selected when the lowest byte (bits 24-31) of the conversion command is set to zero. In the standard configuration, the conversion result is always routed to one of the RFIFOs. A time stamp information can be optionally requested.

**Figure 29-117. Conversion command format for the standard configuration**

**Table 29-127. Conversion command format for the standard configuration — field descriptions**

| Field | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
|-------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| EOQ   | <p>End Of Queue Bit</p> <p><b>NOTE:</b> The EOQ bit is asserted in the last command of a CQueue to indicate to the EQADC that a scan of the CQueue is completed. EOQ instructs the EQADC to reset its current CFIFO transfer counter value (TC_CF) to zero. Depending on the CFIFO mode of operation, the CFIFO status will also change upon the detection of an asserted EOQ bit on the last transferred command - see <a href="#">CFIFO scan trigger modes</a> for details. If both the PAUSE and EOQ bits are asserted in the same command message the respective flags are set, but the CFIFO status changes as if only the EOQ bit were asserted.</p> <p>0 Not the last entry of the CQueue.</p> |

**Table 29-127. Conversion command format for the standard configuration — field descriptions (continued)**

| Field            | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
|------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                  | 1 Last entry of the CQueue.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| PAUSE            | <p>Pause Bit</p> <p>The Pause bit allows software to create sub-queues within a CQueue. When the EQADC completes the transfer of a command with an asserted Pause bit, the CFIFO enters the WAITING FOR TRIGGER state. See <a href="#">CFIFO operation status</a> for a description of the state transitions. The Pause bit is only valid when CFIFO operation mode is configured to single or continuous-scan edge trigger mode.</p> <p><b>Note:</b> If both the PAUSE and EOQ bits are asserted in the same command message the respective flags are set, but the CFIFO status changes as if only the EOQ bit were asserted.</p> <p>0 Do not enter WAITING FOR TRIGGER state after transfer of the current Command Message.</p> <p>1 Enter WAITING FOR TRIGGER state after transfer of the current Command Message.</p>                                             |
| REP              | <p>Repeat/loop Start Point Indication Bit</p> <p>The REP bit is asserted in the command to indicate where is the start point of the sub-queue to be repeated when the streaming mode is enabled. The PAUSE bit indicates the end point of the sub-queue. Therefore, both can occur in the same command or in separated ones. If two or more REP bits are read before a PAUSE bit, this is an error case and the intermediary REP bits are ignored.</p> <p>0 It is not the start point of a loop.</p> <p>1 Indicates the start point of the sub-queue to be repeated.</p>                                                                                                                                                                                                                                                                                              |
| Reserved<br>BN   | <p>Reserved</p> <p>Buffer Number Bit</p> <p>BN indicates which buffer the message will be stored in.</p> <p>0 Message stored in buffer 0.</p> <p>1 Message stored in buffer 1.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| CAL              | <p>CALibration Bit</p> <p>CAL indicates if the returning conversion result must be calibrated.</p> <p>0 Do not calibrate conversion result.</p> <p>1 Calibrate conversion result.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| MESSAGE_TAG[0:3] | <p>MESSAGE_TAG Field</p> <p>The MESSAGE_TAG allows the EQADC to separate returning results into different RFIFOs. <a href="#">Table 29-128</a> describes the meaning of the MESSAGE_TAG. When the EQADC transfers a command, the MESSAGE_TAG is included as part of the command. Eventually on-chip ADC returns the result with the same MESSAGE_TAG. The EQADC separates incoming messages into different RFIFOs by decoding the MESSAGE_TAG of the incoming data.</p> <p><b>Note:</b> The MESSAGE_TAG value can be particularly used in a companion module (that uses the PSI) as the address to the annexed conversion result. The data can be routed to different sub-blocks based on the MESSAGE_TAG, similar to what is done with the RFIFOs in the eQADC. Additionally, in the companion module it is not required to follow <a href="#">Table 29-128</a>.</p> |
| LST[0:1]         | Long Sampling Time                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |

**Table 29-127. Conversion command format for the standard configuration — field descriptions (continued)**

| Field               | Description                                                                                                                                                                                                                                                                                                                                                                                                                         |
|---------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                     | <p>These two bits determine the duration of the sampling time in ADC clock cycles.</p> <p>00          2 sampling cycles (ADC clock cycles)</p> <p>01          8 sampling cycles (ADC clock cycles)</p> <p>10          64 sampling cycles (ADC clock cycles)</p> <p>11          128 sampling cycles (ADC clock cycles)</p>                                                                                                           |
| TSR                 | <p>Time Stamp Request</p> <p>TSR indicates the request for a time stamp. When TSR is asserted, the on-chip <i>ADC Control Logic</i> returns a time stamp for the current conversion command after the conversion result is sent to the RFIFOs. See <a href="#">Time stamp feature</a> for details.</p> <p>0          Return conversion result only.</p> <p>1          Return conversion time stamp after the conversion result.</p> |
| FMT                 | <p>Conversion Data Format</p> <p>FMT specifies to the EQADC how to format the 12-bit conversion data returned by the ADCs into the 16-bit format which is sent to the RFIFOs. See <a href="#">ADC result format for on-chip ADC operation</a> for details.</p> <p>0          Right justified unsigned.</p> <p>1          Right justified signed.</p>                                                                                |
| CHANNEL_NUMBER[0:7] | <p>Channel Number Field</p> <p>The CHANNEL_NUMBER field selects the analog input channel. The software programs this field with the channel number corresponding to the analog input pin to be sampled and converted. See <a href="#">Channel assignment</a> for details.</p>                                                                                                                                                       |

**Table 29-128. MESSAGE\_TAG description**

| MESSAGE_TAG[0:3] | MESSAGE_TAG Meaning                    |
|------------------|----------------------------------------|
| 0b0000           | Result is sent to RFIFO 0              |
| 0b0001           | Result is sent to RFIFO 1              |
| 0b0010           | Result is sent to RFIFO 2              |
| 0b0011           | Result is sent to RFIFO 3              |
| 0b0100           | Result is sent to RFIFO 4              |
| 0b0101           | Result is sent to RFIFO 5              |
| 0b0110 - 0b0111  | Reserved                               |
| 0b1000           | Null Message Received                  |
| 0b1001           | Reserved for customer use <sup>1</sup> |
| 0b1010           | Reserved for customer use <sup>2</sup> |
| 0b1011 - 0b1111  | Reserved                               |

1. These messages are treated as null messages. Therefore, they must obey the format for incoming null messages and return valid BUSY0/1 fields. "

29.6.2.2.1.2 Conversion command format for alternate configurations

Figure 29-118 describes the format for conversion commands when interfacing with the on-chip ADCs in one of the 14 alternate configurations. An alternate configuration is selected when the lowest byte (bits 24-31) of the conversion command is set to a value in the range 0x08-0x15. Each value in this range selects one of the 14 alternate configuration (0x08 selects Alternate Configuration 1, 0x15 selects Alternate Configuration 14). In the alternate configurations, the conversion result can be routed to one of the RFIFOs and/or to the parallel side interface to communicate with an on-chip companion module, or to one or two on-chip companion modules. Bit fields in the corresponding Alternate Configuration Control Register and Extended Alternate Configuration Control Register select the Internal RFIFO or Parallel Side Interface as the destination for the conversion result. A time stamp information can be optionally requested.

All fields, except FFMT and ALT\_CONFIG\_SEL, are identical to the ones in the standard configuration format. Only the fields which are different from the standard format will be described here.

Figure 29-118. Conversion command format for alternate configurations

Table 29-129. Conversion command format for alternate configurations — field descriptions

| Field       | Description      |
|-------------|------------------|
| EOQ         | See Table 29-127 |
| PAUSE       | See Table 29-127 |
| REP         | See Table 29-127 |
| EB          | See Table 29-127 |
| BN          | See Table 29-127 |
| CAL         | See Table 29-127 |
| MESSAGE_TAG | See Table 29-127 |

| FFMT                | <p>Flush or Format</p> <p>The function of this bit depends on the DEST field of the Alternate Configuration Control Register. If DEST is equal to 0b000, then FFMT defines the format in which the 12-bit conversion result are stored in the RFIFOs. If DEST is not equal to 0b000, then the FFMT bit is used to send a flush (soft-reset) signal through the parallel side interface to the companion module addressed by the DEST field.</p> <p>In case DEST is not equal to 0b000, the FMTA bit in the Alternate Configuration Control register is used to define the conversion result format.</p> <p><b>Note:</b> The flush signal can be asserted along with a valid conversion result. In this case the companion module should execute the software-reset first and then consider the conversion result as a valid data for the filtering algorithm.</p> <table> <tr> <td>0</td><td>Conversion Result Format set to right justified unsigned if DEST is equal to 0b000. No flush signal is sent through the side interface if DEST is not equal to 0b000.</td></tr> <tr> <td>1</td><td>Conversion Result Format set to right justified signed if DEST is equal to 0b000. A flush signal is sent through the side interface if DEST is not equal to 0b000.</td></tr> </table> | 0    | Conversion Result Format set to right justified unsigned if DEST is equal to 0b000. No flush signal is sent through the side interface if DEST is not equal to 0b000. | 1    | Conversion Result Format set to right justified signed if DEST is equal to 0b000. A flush signal is sent through the side interface if DEST is not equal to 0b000. |      |                           |      |                           |      |                           |      |                           |      |                           |      |                           |      |                           |      |                            |      |                            |      |                            |      |                            |      |                            |

### 29.6.2.2.1.3 Write configuration command format for on-chip ADC operation

Figure 29-119 describes the command message format for a write configuration command when interfacing with the on-chip ADCs. A write configuration command is used to set the control registers of the on-chip ADCs. No conversion data will be returned for a write configuration command. Write configuration commands are differentiated from read configuration commands by a negated R/W bit.

| Field                       | Description                                                                                                                                                                    |
|-----------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| EOQ                         | End Of Queue Bit                                                                                                                                                               |
| PAUSE                       | Pause Bit                                                                                                                                                                      |
| REP                         | Repeat/loop Start Point Indication Bit                                                                                                                                         |
| BN                          | Buffer Number Bit<br>See <a href="#">Conversion command format for the standard configuration</a> .                                                                            |
| R/W                         | Read/Write bit<br>A negated R/W indicates a write configuration command.<br>0 Write                                                                                            |
| ADC_REGISTER_HIGH_BYTE[0:7] | ADC Register High Byte Field<br>REGISTER_HIGH_BYTE is the value to be written into the most significant 8 bits of control/configuration register when the R/W bit is negated.  |
| ADC_REGISTER_LOW_BYTE[0:7]  | ADC Register Low Byte Field<br>REGISTER_LOW_BYTE is the value to be written into the least significant 8 bits of a control/configuration register when the R/W bit is negated. |
| ADC_REG_ADDRESS[0:7]        | ADC Register Address<br>The ADC_REG_ADDRESS field selects a register on the ADC register set to be written or read. Only half-word addresses can be used.                      |

#### 29.6.2.2.1.4 Read configuration command format for on-chip ADC operation

Figure 29-120 describes the command message format for a read configuration command when interfacing with the on-chip ADCs. A read configuration command is used to read the contents of the on-chip ADC registers which are only accessible via command messages. Read configuration commands are differentiated from write configuration commands by an asserted R/W bit.

**Figure 29-120. Read configuration command format for on-chip ADC operation**

**Table 29-131. Read configuration command format for on-chip ADC operation — field descriptions**

| Field                | Description                                                                                                                                               |
|----------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------|
| EOQ                  | End Of Queue Bit                                                                                                                                          |
| PAUSE                | Pause Bit                                                                                                                                                 |
| REP                  | Repeat/loop Start Point Indication Bit                                                                                                                    |
| BN                   | Buffer Number Bit<br>See <a href="#">Conversion command format for the standard configuration</a> .                                                       |
| R/W                  | Read/Write bit<br>An asserted R/W bit indicates a read configuration command.<br>1 Read                                                                   |

| ADC_REG_ADDRESS[0:7] | ADC Register Address<br>The ADC_REG_ADDRESS field selects a register on the ADC register set to be written or read. Only half-word addresses can be used. |

### 29.6.2.2.1.5 ADC result format for on-chip ADC operation

When the *FIFO Control Unit* receives a return data message, it decodes the MESSAGE\_TAG field and stores the 16-bit data into the appropriate RFIFO. This section describes the *ADC result* portion of the *result message* returned by the on-chip ADCs. The 16-bit data stored in the RFIFOs can be:

- Data read from an ADC register with a read configuration command. In this case, the stored 16-bit data corresponds to the contents of the ADC register that was read.
- A time stamp. In this case, the stored 16-bit data is the value of the time base counter latched when the EQADC detects the end of the analog input voltage sampling. For details see [Time stamp feature](#).
- A conversion result, coming directly from the ADCs. In this case, the stored 16-bit data contains a right justified 14-bit result data. The conversion result can be calibrated or not depending on the status of CAL bit in the command that requested the conversion<sup>4</sup>. When the CAL bit is negated, this 14-bit data is obtained by executing a 2-bit left-shift on the 12-bit data resultant from the resolution adjustment on the 8 or 10 or 12-bit data received from the ADC. The resolution adjustment consists of changing the conversion result input from 8, 10 or 12 bits right aligned to a 12-bit word left aligned - see [ADC resolution selection feature](#) for details. When the CAL bit is asserted, this 14-bit data is the result of the calculations performed in the EQADC MAC unit using the 12-bit data result of the resolution adjustment and the calibration constants GCC and OCC, or ALTGCC and ALTOCC - see [ADC calibration feature](#) for details. Then, this 14-bit data is further formatted into a 16-bit format according to the status of the FMT bit in conversion command of the standard configuration or FFMT bit in the conversion command of the alternate configurations<sup>5</sup>. When FMT/FFMT is asserted, the 14-bit result data is reformatted to look as if it was measured against an imaginary ground at VREF/2 (the MSB bit of the 14-bit result is inverted), and is sign-extended to a 16-bit format as in [Figure 29-121](#). When FMT/FFMT is negated, the EQADC zero-extends the 14-bit result data to a 16-bit format as in [Figure 29-122](#). Correspondence between the analog voltage in a channel and the calculated digital values is shown in [Table 29-133](#).

4. In case the conversion result is routed through an on-chip DSP via side interface, the calibration is applied before the data is sent to the DSP.

5. For simplicity, the following text will refer to FMT only, but when using alternate configurations, see [Conversion command format for alternate configurations](#).

**Figure 29-121. ADC Result Format when FMT=1 (Right Justified Signed)****Figure 29-122. ADC result format when FMT=0 (right justified unsigned)****Table 29-132. ADC result formats — field descriptions**

| Field                   | Description                                                                                                                                                                                                                                   |
|-------------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| SIGN_EXT[0:1]           | Sign Extension field<br><br>SIGN_EXT only has meaning when FMT is asserted. SIGN_EXT is 0b00 when CONVERSION_RESULT is positive, and 0b11 when CONVERSION_RESULT is negative.                                                                 |
| CONVERSION_RESULT[0:13] | Conversion Result field<br><br>CONVERSION_RESULT is a digital value corresponding to the analog input voltage in a channel when the conversion command was initiated. The two's complement representation is used to express negative values. |

In [Table 29-133](#) :

- $V_{REF} = V_{RH} - V_{RL} = 5.12V$ . Resulting in one 12-bit count (LSB) = 1.25mV.
- The two's complement representation is used to express negative values.

1. Assuming uncalibrated conversion results.

### 29.6.3 Command/result queues

The Command and Result queues (CQueues and RQueues) are actually part of the EQADC system although they are not hardware implemented inside the EQADC. Each CQueue entry is a 32-bit Command Message. The last entry of a CQueue has the EOQ bit asserted to indicate that it is the last entry of the CQueue. RQueue entry is a 16-bit data.

See [Overview and basic terminology](#) for a description of the message formats and their flow in EQADC.

See [CQueue and RQueues usage](#) for examples of how CQueues and RQueues can be used.

## 29.6.4 EQADC command FIFOs

### 29.6.4.1 CFIFO basic functionality

There are six prioritized CFIFOs located in the EQADC. Each CFIFO is four entries deep, except CFIFO0 that can be configured to eight entries deep in extended mode, and each CFIFO entry is 32 bits long. A CFIFO serves as a temporary storage location for the command messages stored on the CQueues in the system memory. When a CFIFO is not full, the EQADC sets the corresponding CFFF bit in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#). If CFFE is asserted in [EQADC Interrupt and DMA Control Register 0 \(EQADC\\_IDCR0\)](#), the EQADC generates requests for more commands from a CQueue. An interrupt request, served by the host CPU, is generated when CFFS is negated, and a DMA request, served by the DMAC, is generated when CFFS is asserted. The host CPU or the DMAC respond to these requests by writing to the [EQADC CFIFO Push Register \(EQADC\\_CFPR<sub>n</sub>\)](#) to fill the CFIFO.

#### Note

The DMAC should be configured to write a single command (32-bit data) to the CFIFO push registers for every asserted DMA request it acknowledges. See [EQADC/DMAC interface](#) for DMAC configuration guidelines.

#### Note

CFIFO0 can be configured to work in an alternative way called Streaming Mode. This mode is very different from the mode described here because it maintains some stored commands to execute them several times in sequence and in loop.

#### Note

Only whole words must be written to EQADC\_CFPR. Writing half-words or bytes to EQADC\_CFPR will still push the whole 32-bit CF\_PUSH field into the corresponding CFIFO, but undefined data will fill the areas of CF\_PUSH that were not specifically designated as target locations for writing.

Figure 29-123 describes the important components in the CFIFO. Each CFIFO is implemented as a circular set of registers to avoid the need to move all entries at each push/pop operation. The Push Next Data Pointer points to the next available CFIFO location for storing data written into the EQADC Command FIFO Push Register. The Transfer Next Data Pointer points to the next entry to be removed from CFIFO<sub>x</sub> when it completes a transfer. The *CFIFO Transfer Counter Control Logic* counts the number of entries in the CFIFO and generates DMA or interrupt requests to fill the CFIFO. TNXTPTR in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) indicates the index of the entry that is currently being addressed by the Transfer Next Data Pointer, and CFCTR, in the same register, provides the number of entries stored in the CFIFO. Using TNXTPTR and CFCTR, the absolute addresses for the entries indicated by the Transfer Next Data Pointer and by the Push Next Data Pointer can be calculated using the following formulas:

Transfer Next Data Pointer Address = CFIFO<sub>x</sub>\_BASE\_ADDRESS + TNXTPTR<sub>x</sub>\*4

Push Next Data Pointer Address = CFIFO<sub>x</sub>\_BASE\_ADDRESS + [(TNXTPTR<sub>x</sub> + CFCTR<sub>x</sub>) mod CFIFO\_DEPTH] \* 4

where

- $a \bmod b$  returns the remainder of the division of  $a$  by  $b$ .
- CFIFO<sub>x</sub>\_BASE\_ADDRESS is the smallest memory mapped address allocated to a CFIFO<sub>x</sub> entry.
- CFIFO\_DEPTH is the number of entries contained in a CFIFO - four in this implementation.

When CFS<sub>x</sub> in [EQADC CFIFO Status Register \(EQADC\\_CFSR\)](#) is TRIGGERED, the EQADC generates the proper control signals for the transfer of the entry pointed by Transfer Next Data Pointer. CFUF<sub>x</sub> in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) is set when a CFIFO<sub>x</sub> underflow event occurs. A CFIFO underflow occurs when the CFIFO is in TRIGGERED state and it becomes empty. No commands will be transferred from an underflowing CFIFO, nor will command transfers from lower priority CFIFOs be blocked. CFIFO<sub>x</sub> is empty when the Transfer Next Data Pointer  $x$  equals the Push Next Data Pointer  $x$  and CFCTR<sub>x</sub> is zero. CFIFO<sub>x</sub> is full when the Transfer Next Data Pointer  $x$  equals the Push Next Data Pointer  $x$  and CFCTR<sub>x</sub> is not zero.

When the EQADC completes the transfer of an entry from CFIFO<sub>x</sub>: the transferred entry is popped from CFIFO<sub>x</sub>, the CFIFO counter CFCTR in the [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) is decremented by one, and Transfer Next Data Pointer

x is incremented by one (or wrapped around) to point to the next entry in the CFIFO. The transfer of entries bound for the on-chip ADCs is considered completed when they are stored in the appropriate CBuffer.

When the EQADC\_CFPRx is written and CFIFOx is not full, the CFIFO counter CFCTRx is incremented by one, and the Push Next Data Pointer x then is incremented by one (or wrapped around) to point to the next entry in the CFIFO.

When the EQADC\_CFPRx is written but CFIFOx is full, the EQADC will not increment the counter value and will not overwrite any entry in CFIFOx.

**Figure 29-123. CFIFO Diagram**

The detailed behavior of the Push Next Data Pointer and Transfer Next Data Pointer is described in the example shown in [Figure 29-124](#) where a CFIFO with 16 entries is shown for clarity of explanation, the actual hardware implementation has only four entries. In this example, CFIFOx with 16 entries is shown in sequence after pushing and transferring entries.

Figure 29-124. CFIFO Entry Pointer Example

### 29.6.4.2 CFIFO0 streaming mode description

CFIFO0 can be configured to operate in streaming mode to allow repetition of a group of commands several times without the need of refilling the registers as in the normal mode of operation of CFIFOs. This mode makes use of the additional bit in the Conversion Command Word (CCW) called 'Repeat' (REP bit). The purpose of this bit is to mark in the command queue, where to start a repeating sequence. This location is stored in an additional pointer 'Repeat Pointer'.

Streaming mode requires 2 trigger inputs. The standard queue 0 trigger, in this mode referred to as Repeat Trigger and a new internal trigger input to the eQADC called Advance Trigger (no filter available).

CFIFO0 is configured to operate in streaming mode by setting the bit STRME0 as described in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#). CFIFO0 is eight entries deep in extended mode by setting the bit CFEEE0 in the same EQADC\_CFCR register, and each entry is 32 bits long. This CFIFO0 serves as a local storage of a few commands that need to be executed sequentially as in a FIFO but can contain sub-queues that need to be executed several times. The CFFF0 bit in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) is used to assure the CFIFO0 is not full and command messages are stored from address 0x0 to 0x7.

#### 29.6.4.2.1 CFIFO0 operation in streaming mode

In Streaming mode, the CFIFO0 is filled with CCWs using the DMA exactly the same as existing modes. The CFIFO executes commands as per the existing modes until it executes a Conversion Command Word with the Repeat bit set. When this CCW is executed, the Repeat Pointer is set to point to this FIFO location and from this CCW onwards, CFIFO0 entries is not invalidated, that is, the Repeat Pointer prevents this and subsequent entries from being overwritten.

The queue continues to execute until a CCW with an asserted Pause bit is completed; then the queue stops and enters the Pause state, waiting for a trigger. This is the same as normal behavior.

The Pause state is exited in one of two ways: Repeat Trigger or Repeat Trigger with Advance Trigger. The Repeat trigger with no Advance trigger causes the Transfer Next Data Pointer to be loaded with the Repeat Pointer location and CCWs are then executed from the Repeat Pointer back to the Pause bit. This means that a section of the CFIFO0 is repeatedly executed every time a Repeat Trigger occurs.

The Repeat trigger with the Advance trigger pending causes all CCWs from the Repeat pointer to the Pause bit to be invalidated and the CCW after the pause bit to be executed. This is achieved by invalidating the Repeat Pointer. The effect is that the queue advances beyond the repeating section of the CFIFO0 to execute new CCWs.

Note that the Advance trigger can occur at any time between Repeat triggers, but is only granted when the next Repeat trigger occurs. Prior to that it is pending.

In a typical application, the queue is made of some configuration commands to the ADC (to flush the decimator or turn on pad pull-up/down) followed by a repeating section of ADC conversions on one or more ADC channels from one or more sensors; followed by a few more configuration commands; then more repeating ADC conversions, until the

entire engine cycle is complete; when the queue is restarted. The mechanism described permits any number of repeating sub-queues to be loaded and executed, interspersed by configuration commands.

#### 29.6.4.2.2 Triggering description in streaming mode

The additional trigger signal ATRIG0 is detected by a separate circuit that is configured by the bit field AMODE0 as described in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#). This trigger signal is used as an advance control of pop pointer of CFIFO0. In addition, it is used as the enable trigger for the Repeat trigger. This means it is necessary to have an Advance trigger first to enable the detection of the Repeat trigger. When the Repeat trigger is enabled, the Advance trigger is used to advance the pop pointer beyond some loop sub-queue. And it is used to disable the Repeat trigger by executing a Pause without a previous REP bit. [Figure 29-125](#) and [Figure 29-126](#) illustrate these two triggers dependency.

**Figure 29-125. Advance trigger and repeat trigger relationship Block Diagram**

In Streaming mode, the CFIFO0 is filled with CCWs using the DMA as usual. The two triggers are configured to positive edge and single scan mode.

The SSS bit is asserted and the trigger detector of the Repeat trigger is disabled in the start of the queue. It is necessary to receive the first Advance trigger to enable the detector of the other trigger. This enable is useful when the Repeat trigger is received all the time and the trigger signal can be disabled when it is not desired.

The Advance trigger is received and detected and the Repeat trigger detector is enabled. No commands are executed until now.

The Repeat trigger is detected and the commands start to be executed in sequence. If a REP bit is decoded with the PAUSE bit, the loop is configured and the CFIFO0 commands stop to be executed. The next Repeat trigger is waited to start the execution of the loop again, or the Advance trigger can be detected to break the loop and advance the queue in CFIFO0. The Repeat trigger detector remains enabled.

If the Advance trigger is received and the next command in the CFIFO0 does not present the REP bit set, this means the CFIFO0 is not starting a new loop. In this case (outside a loop) if a PAUSE bit is decoded, this means to disable the Repeat trigger detector. This can be useful if the Repeat trigger is not required for some interval of time. The Repeat trigger detector is enabled again when the next Advance trigger event is detected.

**Figure 29-126. Timing diagram of typical use of Advance trigger and Repeat trigger**

#### 29.6.4.2.3 CFIFO0 diagram description in streaming mode

Figure 29-127 represents the main components of CFIFO0 in streaming mode. However, some signals behave in a different way from the common operation. The Push Next Data Pointer points to the next available CFIFO0 location for storing data written into the EQADC Command FIFO Push Register. The Transfer Next Data Pointer points to the next entry to be transferred to Cbuffer. The Repeat Pointer points to the first entry of the repeating sub-queue. TNXTPTR in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) indicates the index of the entry that is currently being addressed by the Transfer Next Data Pointer, and CFCTR, in the same register, provides the number of entries stored in the CFIFO.

When CFS0 in [EQADC CFIFO Status Register \(EQADC\\_CFSR\)](#) is TRIGGERED, the EQADC generates the proper control signals for the transfer of the entry pointed by Transfer Next Data Pointer. CFUF0 in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) is set when CFIFO0 underflow event occurs. A CFIFO underflow occurs when the CFIFO is in TRIGGERED state and it is empty. No commands will be transferred from an underflowing CFIFO, nor will command transfers from lower priority CFIFOs be blocked. CFIFO0 is empty when CFCTR0 is zero. CFIFO0 is full when (CFCTR0 mod CFIFO\_DEPTH) is zero but CFCTR0 is not zero.

When the EQADC completes the transfer of an entry from CFIFO0 in loop condition: the transferred entry is not popped from CFIFO0, the CFIFO counter CFCTR in the [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) is not decremented by one, and Transfer Next Data Pointer 0 is incremented by one (or wrapped around) to point to the next entry in the CFIFO0.

**Figure 29-127. CFIFO0 in streaming mode diagram**

The detailed behavior of the Push Next Data Pointer and Transfer Next Data Pointer is described in the example shown in [Figure 29-128](#) where a CFIFO with 16 entries is shown for clarity of explanation, the actual hardware implementation has only four/eight entries. In this example, CFIFO0 with 16 entries is shown in sequence after pushing and transferring entries.

**Figure 29-128. CFIFO0 in streaming mode entry pointer example**

Figure 29-129. CFIFO0 in streaming mode entry pointer example (continued)

#### 29.6.4.2.4 Streaming mode error conditions

In the repeat state, the existing error conditions still apply, but now there are new ways to trigger them. Now, the CCWs are not being invalidated so the DMA is not able to load more CCWs into those locations. So a queue overflow becomes more likely, and occurs if the repeat loop is longer than 8 entries. If all CCWs in the CFIFO0 are executed and no Pause bit or EOQ bit is detected, the eQADC will signal an underflow error. In practice this may limit a repeating queue to 7 entries since otherwise an underflow will occur at the point a Repeat with Advance trigger occurs, and there is no command in the CFIFO0 to execute. The exception is a final command with both a Pause and an EOQ bit set. The End of Queue bit EOQ continues to operate as in normal mode, unless the Repeat mode is enabled. In this case the Pause bit takes precedence and a Repeat trigger causes the jump back described. A Repeat trigger with Advance trigger causes the queue to end.

Another error condition occur when the repeat trigger is in the TRIGGERED state and a new repeat trigger is received. In this case, a trigger overflow occurs but the CFIFO0 is defined to not restart the loop. The trigger in this case is not used in the CFIFO0, but the overflow is indicated.

### 29.6.4.3 CFIFO common prioritization and command transfer

The CFIFO priority is fixed according to the CFIFO number. A CFIFO with a smaller number has a higher priority. When commands of distinct CFIFOs are bound for the same destination (CBuffer), the higher priority CFIFO is always served first. A TRIGGERED, not-underflowing CFIFO will start the transfer of its commands when:

- its commands are bound for an internal CBuffer that is not full, and it is the highest priority triggered CFIFO sending commands to that CBuffer.

A triggered CFIFO with commands bound for a certain CBuffer consecutively transfers its commands to it until:

- an asserted End Of Queue bit is reached, or;
- an asserted Pause bit is encountered and the CFIFO is configured for edge trigger mode, or;
- CFIFO is configured for level trigger mode and a closed gate is detected, or;
- in case its commands are bound for an internal CBuffer, a higher priority CFIFO that uses the same internal CBuffer is triggered

The prioritization logic of the EQADC, depicted in [Figure 29-130](#), is composed of three independent sub-blocks: one prioritizing CFIFOs with commands bound for CBuffer0, another prioritizing CFIFOs with commands for CBuffer1. As these two sub-blocks are independent, simultaneous writes to CBuffer0, to CBuffer1 are allowed. The hardware identifies the destination of a command by decoding the BN bit in the command message - see [Message format in EQADC](#) for details.

#### Note

Triggered but empty CFIFOs, underflowing CFIFOs, are not considered for prioritization. No data from these CFIFOs will be sent to the CBuffers and nor will they stop lower priority CFIFOs from transferring commands.

Whenever CBuffer0 is able to receive new entries, the prioritization sub-block selects the highest-priority triggered CFIFO with a command bound for CBuffer0, and writes its command into the buffer. In case CBuffer0 is able to receive new entries but there are no triggered CFIFOs with commands bound for it, nothing is written to the buffer. The sub-block prioritizing CBuffer1 usage behaves in the same way.

Figure 29-130. CFIFO prioritization logic

#### 29.6.4.4 CFIFO prioritization in abort mode

The CFIFO priority does not change when the EQADC is configured to allow abortion of conversion execution in on-chip ADC analog blocks. However, CFIFO0 is the only one that can be enabled to abort conversions.

This feature is necessary when the timing of some conversion is very important. In normal priority scheme, when CFIFO0 is triggered, its conversion command can be put behind 2 pending conversion commands in the Cbuffer due to the queue structure. Considering that these 2 pending commands are from lower priority CFIFOs and that the delay between the trigger and the sampling of the command from CFIFO0 can be unacceptable, EQADC can be configured to permit immediate conversion commands from CFIFO0 with abort function.

When CFIFO0 is triggered and abort is enabled, up to 2 commands in Cbuffer0 or Cbuffer1 are stored in a side register. The abort request signal is generated to ADC0 or ADC1 and the confirmation of ADC reset/ready is waited to send the command from CFIFO0 to the decoded Cbuffer.

After the transfer of all commands from CFIFO0, the recovery phase restores the up to 2 commands that were in Cbuffer when the abort occurred. After this recovery phase, it is established the normal process of prioritization of commands from CFIFOs.

### 29.6.4.5 External trigger event detection

The digital filters for trigger signals can be individually bypassed by asserting the input control signals eqadc\_intern\_trig\_sel5-0. When the filter is bypassed, the ETRIG input signal is not filtered and the logic after the filter receives a copy of this input trigger signal.

The Digital Filter Length field in [EQADC External Trigger Digital Filter Register \(EQADC\\_ETDFR\)](#) specifies the minimum number of system clocks that the ETRIG0-5 signals must be held at a logic level to be recognized as valid. All ETRIG signals are filtered. A counter for each queue trigger is implemented to detect a transition between logic levels. The counter counts at the system clock rate. The corresponding counter is cleared and restarted each time the signal transitions between logic levels. When the corresponding counter matches the value specified by the Digital Filter Length field in [EQADC External Trigger Digital Filter Register \(EQADC\\_ETDFR\)](#), the EQADC considers the ETRIG logic level to be valid and passes that new logic level to the rest of the EQADC.

The filter is only for filtering the ETRIG signal. Logic after the filter checks for transitions between filtered values, such as for detecting the transition from a filtered logic level zero to a filter logic level one in rising edge external trigger mode. The EQADC can detect rising edge, falling edge, or level gated external triggers. The digital filter will always be active independently of the status of the MODEx field in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#), but the edge, level detection logic is only active when MODEx is set to a value different from disabled, and in case MODEx is set to single scan mode, when the SSS bit is asserted. Note that the time necessary for an external trigger event to result into a CFIFO status change is not solely determined by the DFL field in the [EQADC External Trigger Digital Filter Register \(EQADC\\_ETDFR\)](#). After being synchronized to the system clock and filtered, a trigger event is checked against the CFIFO trigger mode. Only then, after a valid trigger event is detected, the EQADC accordingly changes the CFIFO status. See [Figure 29-131](#) for an example.

Obs.

- 1: This delay is about 2 clocks when the filter bypass control is asserted.

**Figure 29-131. ETRIG event propagation example**

### 29.6.4.6 CFIFO scan trigger modes

The EQADC supports two different scan modes, single-scan and continuous-scan. Refer to [Table 29-134](#) for a summary of these two scan modes. When a CFIFO is triggered, the EQADC scan mode determines whether the EQADC will stop command transfers from a CFIFO, and wait for software intervention to rearm the CFIFO to detect new trigger events, upon detection of an asserted EOQ bit in the last transfer. See [Message format in EQADC](#) for details about command formats.

CFIFOs can be configured in single-scan or continuous-scan mode. When a CFIFO is configured in single-scan mode, the EQADC scans the CQueue one time. The EQADC stops future command transfers from the triggered CFIFO after detecting the EOQ bit set in the last transfer. After a EOQ bit is detected, software involvement is required to rearm the CFIFO so that it can detect new trigger events.

When a CFIFO is configured for continuous-scan mode, no software involvement is necessary to rearm the CFIFO to detect new trigger events after an asserted EOQ is detected. In continuous-scan mode the whole CQueue is scanned multiple times.

The EQADC also supports different triggering mechanisms for each scan mode. The EQADC will not transfer commands from a CFIFO until the CFIFO is triggered. The combination of scan modes and triggering mechanisms allows the support of different requirements for scanning input channels. The scan mode and trigger mechanism are configured by programming the MODEx field in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#).

Enabled CFIFOs can be triggered by software or external trigger events. The elapsed time from detecting a trigger to transferring a command is a function of clock frequency, trigger synchronization, trigger filtering or not, programmable trigger events, command

transfer, CFIFO prioritization, CBuffer availability, etc. Fast and predictable transfers can be achieved by ensuring that the CFIFO is not underflowing and that the target CBuffer is not full when the CFIFO is triggered.

#### 29.6.4.6.1 Disabled Mode

The MODEx field in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#) for all of the CFIFOs can be changed from any other mode to disabled at any time. No trigger event can initiate command transfers from an CFIFO which has its MODE field programmed to disabled.

#### Note

If MODEx is not disabled, it must not be changed to any other mode besides disabled. If MODEx is disabled and the CFIFO status is IDLE, MODEx can be changed to any other mode.

If MODEx is changed to disabled:

- The CFIFO execution status will change to IDLE. The timing of this change depends on whether a command is being transferred or not:
  - When no command transfer is in progress, the EQADC switches the CFIFO to IDLE status immediately.
  - When a command transfer to an on-chip CBuffer is in progress, the EQADC will complete the transfer, update TC\_CF, and switch CFIFO status to IDLE. Command transfers to the internal CBuffers are considered completed when a command is written to the buffers.
- The CFIFOs are not invalidated automatically. The CFIFO still can be invalidated by writing a "1" to the CFINVx bit in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#). Certify that CFS has changed to IDLE before setting CFINVx.
- The TC\_CFx value also is not reset automatically, but it can be reset by writing "0" to it.
- The SSS bit in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISRn\)](#) is negated. The SSS bit can be set even if a "1" is written to the SSE bit in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#) in the same write that the MODEx field is changed to a value other than disabled.
- The trigger detection hardware is reset. If MODEx is changed from disabled to an edge trigger mode, a new edge, matching that edge trigger mode, is needed to trigger the command transfers from the CFIFO.

## Note

CFIFO fill requests, which generated when CFFF is asserted, are not automatically halted when MODE<sub>x</sub> is changed to disabled. CFIFO fill requests will still be generated until CFFE is cleared in [EQADC Interrupt and DMA Control Register 0 \(EQADC\\_IDCR0\)](#).

### 29.6.4.6.2 Single-scan mode

In single-scan mode, a single pass through a sequence of command messages in a CQueue is performed.

In single-scan software trigger mode, the CFIFO is triggered by an asserted Single-Scan Status bit (SSS) in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#). The SSS bit is set by writing "1" to the Single-Scan Enable bit (SSE) in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#).

In single-scan edge- or level-trigger mode, the respective triggers are only detected when the SSS bit is asserted. When the SSS bit is negated, all trigger events for that CFIFO are ignored. Writing a "1" to the SSE bit can be done during the same write cycle that the CFIFO operation mode is configured.

Only the EQADC can clear the SSS bit. Once SSS is asserted, it remains asserted until the EQADC completes the CQueue scan, or the CFIFO operation mode (MODE<sub>x</sub>) in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#) is changed to disabled. The SSS<sub>x</sub> bit will be negated while MODE<sub>x</sub> is disabled.

#### 29.6.4.6.2.1 Single-Scan Software Trigger

When single-scan software trigger mode is selected, the CFIFO is triggered by an asserted SSS bit. The SSS bit is asserted by writing "1" to the SSE bit. Writing to SSE while SSS is already asserted will not have any effect on the state of the SSS bit, nor will it cause a trigger overrun event.

The CFIFO commands start to be transferred when the CFIFO becomes the highest priority CFIFO using a not-full on-chip CBuffer. When an asserted EOQ bit is encountered, the EQADC will clear the SSS bit. Setting the SSS bit is required for the EQADC to start the next scan of the queue.

The Pause bit has no effect in single-scan software trigger mode.

#### 29.6.4.6.2.2 Single-scan edge trigger

When SSS is asserted and an edge triggered mode is selected for a CFIFO, an appropriate edge on the associated trigger signal causes the CFIFO to become TRIGGERED. For example, if rising-edge trigger mode is selected, the CFIFO becomes TRIGGERED when a rising edge is sensed on the trigger signal. The CFIFO commands start to be transferred when the CFIFO becomes the highest priority CFIFO using a not-full on-chip CBuffer.

When an asserted EOQ bit is encountered, the EQADC clears SSS and stops command transfers from the CFIFO. An asserted SSS bit and a subsequent edge trigger event are required to start the next scan for the CFIFO. When an asserted Pause bit is encountered, the EQADC stops command transfers from the CFIFO, but SSS remains set. Another edge trigger event is required for command transfers to continue. A trigger overrun happens when the CFIFO is in TRIGGERED state and an edge trigger event is detected.

#### 29.6.4.6.2.3 Single-scan level trigger

When SSS is asserted and a level gated trigger mode is selected, the input level on the associated trigger signal puts the CFIFO in TRIGGERED state. When the CFIFO is asserted to high-level gated trigger, a high level signal opens the gate, and a low level closes the gate. When the CFIFO is set to low-level gated trigger mode, a low level signal opens the gate, and a high level closes the gate. If the corresponding level is already present, setting the SSS bit triggers the CFIFO. The CFIFO commands start to be transferred when the CFIFO becomes the highest priority CFIFO using a not-full on-chip CBuffer.

The EQADC clears the SSS bit and stops transferring commands from a TRIGGERED CFIFO when an asserted EOQ bit is encountered or when CFIFO status changes from TRIGGERED due to the detection of a closed gate. If a closed gate is detected while no command transfers are taking place and the CFIFO status is TRIGGERED, the CFIFO status is immediately changed to IDLE, the SSS bit is negated, and the PF flag is asserted. Once the transmission is completed, the TC\_CF counter is updated, the SSS bit is negated, the PF flag is asserted, and the CFIFO status is changed to IDLE. An asserted SSS bit and a level trigger are required to restart the CFIFO. Command transfers will restart from the point they have stopped.

The Pause bit has no effect in single-scan level-trigger mode.

### 29.6.4.6.3 Continuous-scan mode

In continuous-scan mode, multiple passes looping through a sequence of command messages in a CQueue are executed. When a CFIFO is programmed for a continuous-scan mode, the SSE bit in the [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#) does not have any effect.

#### 29.6.4.6.3.1 Continuous-scan software trigger

When a CFIFO is programmed to continuous-scan software trigger mode, the CFIFO is triggered immediately. The CFIFO commands start to be transferred when the CFIFO becomes the highest priority CFIFO using a not-full on-chip CBuffer. When a CFIFO is programmed to run in continuous-scan software trigger mode, the EQADC will not halt transfers from the CFIFO until the CFIFO operation mode is modified to disabled or a higher priority CFIFO preempts it. Although command transfers will not stop upon detection of an asserted EOQ bit, the EOQF is set and, if enabled, an EOQ interrupt request is generated.

The Pause bit has no effect in continuous-scan software trigger mode.

#### 29.6.4.6.3.2 Continuous-scan edge trigger

When rising, falling, or either edge trigger mode is selected for a CFIFO, a corresponding edge on the associated ETRIG signal places the CFIFO in TRIGGERED state. The CFIFO commands start to be transferred when the CFIFO becomes the highest priority CFIFO using a not-full on-chip CBuffer.

When an EOQ or a Pause is encountered, the EQADC halts command transfers from the CFIFO and, if enabled, the appropriate interrupt requests are generated. Another edge trigger event is required to resume command transfers but no software involvement is required to rearm the CFIFO in order to detect such event.

A trigger overrun happens when the CFIFO is already in TRIGGERED state and a new edge trigger event is detected.

#### 29.6.4.6.3.3 Continuous-scan level trigger

When high or low level gated trigger mode is selected, the input level on the associated trigger signal places the CFIFO in TRIGGERED state. When high-level gated trigger is selected, a high-level signal opens the gate, and a low level closes the gate. The CFIFO commands start to be transferred when the CFIFO becomes the highest priority CFIFO.

using a not-full on-chip CBuffer. Although command transfers will not stop upon detection of an asserted EOQ bit at the end of a command transfer, the EOQF is asserted and, if enabled, an EOQ interrupt request is generated.

The EQADC stops transferring commands from a TRIGGERED CFIFO when CFIFO status changes from TRIGGERED due to the detection of a closed gate. If a closed gate is detected while no command transfers are taking place and the CFIFO status is TRIGGERED, the CFIFO status is immediately changed to WAITING FOR TRIGGER and the PF flag is asserted. Once the transmission is completed, the TC\_CF counter is updated, the PF flag is asserted, and the CFIFO status is changed to WAITING FOR TRIGGER. Command transfers will restart as the gate opens.

The Pause bit has no effect in continuous-scan level-trigger mode.

#### 29.6.4.6.4 CFIFO scan trigger mode start/stop summary

Table 29-134 summarizes the start and stop conditions of command transfers from CFIFOs for all of the single-scan and continuous-scan trigger modes.

**Table 29-134. CFIFO scan trigger mode - command transfer start/stop summary**

| Trigger mode             | Requires asserted SSS to recognize trigger events? | Command transfer start/restart condition                          | Stop on asserted EOQ bit <sup>1</sup> ? | Stop on asserted Pause bit <sup>2</sup> ? | Other command transfer stop condition <sup>3,4</sup>                                                                                   |
|--------------------------|----------------------------------------------------|-------------------------------------------------------------------|-----------------------------------------|-------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------|
| Single Scan Software     | Don't Care                                         | Asserted SSS bit.                                                 | Yes                                     | No                                        | None.                                                                                                                                  |
| Single Scan Edge         | Yes                                                | A corresponding edge occurs when the SSS bit is asserted.         | Yes                                     | Yes                                       | None.                                                                                                                                  |
| Single Scan Level        | Yes                                                | Gate is opened when the SSS bit is asserted.                      | Yes                                     | No                                        | EQADC also stops transfers from the CFIFO when CFIFO status changes from TRIGGERED due to the detection of a closed gate. <sup>5</sup> |
| Continuous Scan Software | No                                                 | CFIFO starts automatically after being configured into this mode. | No                                      | No                                        | None.                                                                                                                                  |
| Continuous Scan Edge     | No                                                 | A corresponding edge occurs.                                      | Yes                                     | Yes                                       | None.                                                                                                                                  |

1. See [CQueue completion status](#) for more information on EOQ.

## CFIFO and trigger status

2. See [Pause status](#) for more information on Pause.
3. EQADC always stops command transfers from a CFIFO when the CFIFO operation mode is disabled.
4. EQADC always stops command transfers from a CFIFO when a higher priority CFIFO is triggered. See [CFIFO common prioritization and command transfer](#) for information on CFIFO priority.
4. If a closed gate is detected while no command transfers are taking place, it will have immediate effect on the CFIFO status.

### 29.6.4.7 CFIFO and trigger status

#### 29.6.4.7.1 CFIFO operation status

Each CFIFOs has its own CFIFO status field. CFIFO status (CFS) can be read from [EQADC CFIFO Status Register \(EQADC\\_CFSR\)](#). [Figure 29-132](#) and [Table 29-135](#) indicate the CFIFO status switching condition. See [Table 29-42](#) for the meaning of each CFIFO operation status. The last CFIFO to transfer a command to an on-chip CBuffer can be read from the LCFTCB $n$  ( $n=0,1$ ) fields in [EQADC CFIFO Status Snapshot Register 0 \(EQADC\\_CFSSR0\)](#).

#### 29.6.4.7.2 CQueue completion status

The End of Queue Flag (EOQF) in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) is asserted when the EQADC completes the transfer of a CFIFO entry with an asserted EOQ bit. Software sets the EOQ bit in the last Command Message of a CQueue to indicate that this entry is the end of the CQueue - see [Message format in EQADC](#) for information on command message formats. The transfer of entries bound for the on-chip ADCs is considered completed when they are stored in the appropriate CBuffer.

The command with a EOQ bit asserted is valid and will be transferred. When EOQIE in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#) and EOQF are asserted, the EQADC will generate an End of Queue interrupt request.

In single-scan modes, command transfers from the corresponding CFIFO will cease when EQADC completes the transfer of a entry with an asserted EOQ. Software involvement is required to rearm the CFIFO so that it can detect new trigger events.

#### Note

An asserted EOQF<sub>x</sub> only implies that EQADC has finished transferring a command with an asserted EOQ bit from CFIFO<sub>x</sub>. It does not imply that result data for the current command and for all previously transferred commands has been returned to the appropriate RFIFO.

#### 29.6.4.7.3 Pause status

In edge trigger mode, when the EQADC completes the transfer of a CFIFO entry with an asserted Pause bit, the EQADC will stop future command transfers from the CFIFO and set the corresponding Pause Flag (PF) in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#). See [Message format in EQADC](#) for information on command message formats. The EQADC ignores the Pause bit in command messages in any software and external level trigger mode. The EQADC sets the PF flag upon detection of

an asserted Pause bit only in single or continuous-scan edge trigger mode. When the PF flag is set for a CFIFO in single-scan edge trigger mode, the SSS bit will not be cleared in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#).

In level trigger mode, the definition of the PF flag has been redefined. In level trigger mode, when CFIFO<sub>x</sub> is in TRIGGERED status, PF<sub>x</sub> is set when CFIFO status changes from TRIGGERED due to detection of a closed gate. The pause flag interrupt routine can be used to verify if the a complete scan of the CQueue was performed. If a closed gate is detected while no command transfers are taking place, it will have immediate effect on the CFIFO status.

When PIE in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#) and PF are asserted, the EQADC will generate a Pause interrupt request.

### Note

In edge trigger mode, an asserted PF<sub>x</sub> only implies that the EQADC finished transferring a command with an asserted PAUSE bit from CFIFO<sub>x</sub>. It does not imply that result data for the current command and for all previously transferred commands has been returned to the appropriate RFIFO.

### Note

In software or level trigger mode, when the EQADC completes the transfer of an entry from CFIFO<sub>x</sub> with an asserted Pause bit, PF<sub>x</sub> will not be set and command transfers will continue without pausing.

#### 29.6.4.7.4 Trigger overrun status

When a CFIFO is configured for edge- or level-trigger mode and is in TRIGGERED state, an additional trigger occurring for the same CFIFO results in a trigger overrun. The trigger overrun bit for the corresponding CFIFO will be set (TORF<sub>x</sub> = 1) in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#). When TORIE in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#) and TORF are asserted, the EQADC generates a trigger overrun interrupt request.

### Note

The trigger overrun flag will not set for CFIFOs configured for software trigger mode.

#### 29.6.4.7.5 Command sequence non-coherency detection

The EQADC provides a mechanism to indicate if a command sequence has been completely executed without interruptions. A command sequence is defined as a group of consecutive commands bound for the same CBuffer and it is expected to be executed without interruptions. A command sequence is coherent if its commands are executed in order without interruptions. Since commands are stored in the CBuffers before being executed in the EQADC, a command sequence is coherent if, while it is transferring commands to a CBuffer, the buffer is only fed with commands from that sequence without ever becoming empty.

A command sequence starts when:

- a CFIFO in TRIGGERED state transfers its first command to CBuffer.
- the CFIFO is constantly transferring commands and the previous command sequence ended.
- the CFIFO resumes command transfers after being interrupted.

And a command sequence ends when:

- an asserted EOQ bit is detected on the last transferred command.
- CFIFO is in edge-trigger mode and asserted PAUSE bit is detected on the last transferred command.
- the CBuffer to which the next command is bound is different from the one to which the last command was transferred.

[Figure 29-133](#) shows examples of how the EQADC would detect command sequences when transferring commands from a CFIFO to a CBuffer. The smallest possible command sequence can have a single command as shown in example 3 of [Figure 29-133](#).

CQueue with a two  
command sequences

|                         |
|-------------------------|
| CF5_CB1_CM0             |
| CF5_CB1_CM1             |
| CF5_CB1_CM2             |
| CF5_CB1_CM3 (Pause = 1) |
| CF5_CB1_CM4             |
| CF5_CB1_CM5             |
| CF5_CB1_CM6 (EOQ = 1)   |

### Example 1

Assuming that these commands are transferred by a CFIFO configured for edge trigger mode and the command transfers are never interrupted, the EQADC would check for non-coherency of two command sequences: one formed by commands 0, 1, 2, 3, and the other by commands 4, 5, 6.

CQueue with a three  
command sequences

|                       |
|-----------------------|
| CF5_CB1_CM0           |
| CF5_CB1_CM1           |
| CF5_CB1_CM2           |
| CF5_CP5_CB0_CM3       |
| CF5_CB0_CM4           |
| CF5_CB1_CM5           |
| CF5_CB1_CM6 (EOQ = 1) |

### Example 2

Assuming that command transfers from the CFIFO are never interrupted, the EQADC would check for non-coherency of three command sequences. The first being formed by commands 0, 1, 2, the second by commands 3, 4 and the third by commands 5, 6. Note that even when the commands of this CQueue are transferred through a CFIFO in continuous-scan mode, the first three commands and the last two commands of this CQueue would still constitute two distinct command sequences, although they are all bound for the same CBuffer, since an asserted EOQ ends a command sequence.

CQueue with a seven  
command sequences

|                       |
|-----------------------|
| CF5_CB1_CM0           |
| CF5_CB2_CM1           |
| CF5_CB3_CM2           |
| CF5_CF5_CB1_CM3       |
| CF5_CB0_CM4           |
| CF5_CB2_CM5           |
| CF5_CB1_CM6 (EOQ = 1) |

### Example 3

The EQADC would check for non-coherency of seven command sequences, all containing a single command, but NCF would never get set.

CF<sub>x</sub>CB<sub>a</sub>CM<sub>n</sub> - Command *n* in CFIFO<sub>x</sub> bound for CBuf

**Figure 29-133. Command sequence examples**

The NCF flag is used to indicate command sequence non-coherency. When the NCF<sub>x</sub> flag is asserted, it indicates that the command sequence being transferred through CFIFO<sub>x</sub> became non-coherent. The NCF flag only becomes asserted for CFIFOs in TRIGGERED state.

A command sequence is non-coherent when, after transferring the first command of a sequence from a CFIFO to a CBuffer, it cannot successively send all the other commands of the sequence before any of the following conditions are true:

- The CFIFO through which commands are being transferred is preempted by a higher priority CFIFO which sends commands to the same CBuffer. The NCF flag becomes asserted immediately after the first command transfer from the preempting CFIFO, that is the higher priority CFIFO, to the CBuffer in use is completed. See [Figure 29-134](#).
- 

Once a command sequence starts to be transferred, the EQADC will check for the command sequence coherency until the command sequence ends or until one of the conditions below becomes true.

- The command sequence became non-coherent.
- The CFIFO status changed from TRIGGERED.
- The CFIFO underflew.

Once command transfers restart/continue, the non-coherency hardware will behave as if the command sequence started from that point. [Figure 29-135](#) depicts how the non-coherency hardware will behave when a non-coherency event is detected.

### Note

If MODEx is changed to disabled while a CFIFO is transferring commands, the NCF flag for that CFIFO will not become asserted.

(a) CFIFO0 and CFIFO5 both have commands to be sent to CBuffer1, and both are not triggered

(b) CFIFO5 becomes triggered and transfers two commands to CBuffer1

(c) CFIFO0 becomes triggered and transfers a command to CBuffer1. The sequence sent through CFIFO5 becomes non-coherent.

\* TNXTPTR - Transfer Next Data Pointer  
CF<sub>x</sub>\_CB<sub>a</sub>\_CM<sub>n</sub> - Command *n* in CFIFO<sub>x</sub> bound for CBuf

**Figure 29-134. Non-coherency event when different CFIFOs use the same CBuffer**

**Figure 29-135. Non-coherency detection when transfers from a command sequence are interrupted**

### 29.6.5 EQADC result FIFOs

#### 29.6.5.1 RFIFO basic functionality

There are six RFIFOs located in the EQADC. Each RFIFO is four entries deep, and each RFIFO entry is 16 bits long. Each RFIFO serves as a temporary storage location for the one of the RQueues allocated in system memory. Result data is saved in the RFIFOs before being moved into the system RQueues. When an RFIFO is not empty, the EQADC sets the corresponding RFDF bit in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#). If RFDE is asserted in [EQADC Interrupt and DMA Control Register 0 \(EQADC\\_IDCR0\)](#), the EQADC generates a request so that an RFIFO entry is moved to the RQueue. An interrupt request, served by the host CPU, is generated when RFDS is negated, and a DMA request, served by the DMAC, is generated when RFDS is asserted. The host CPU or the DMAC responds to these requests by reading [EQADC Result FIFO Pop Register \(EQADC\\_RFPR<sub>n</sub>\)](#) to retrieve data from the RFIFO.

**Note**

The DMAC should be configured to read a single result (16-bit data) from the RFIFO pop registers for every asserted DMA request it acknowledges. See [EQADC/DMAC interface](#) for DMAC configuration guidelines.

**Note**

Reading a word, a half-word, or any bytes from EQADC\_RFPRx will pop an entry from RFIFOx, and the RFCTRx field will be decremented by one.

**Note**

When the DMA is selected ((RFDSx=1), readings should be done only controlled by the DMA protocol. Other ways to flush the RFIFOx to empty the memory can cause a locked DMA request (permanent ON).

Figure 29-136 describes the important components in the RFIFO. Each RFIFO is implemented as a circular set of registers to avoid the need to move all entries at each push/pop operation. The Pop Next Data Pointer always points to the next RFIFO message to be retrieved from the RFIFO when reading EQADC\_RFPR. The Receive Next Data Pointer points to the next available RFIFO location for storing the next incoming message from the on-chip ADCs. The *RFIFO Counter Logic* counts the number of entries in RFIFO and generates interrupt or DMA requests to drain the RFIFO.

POPNXTPTR in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) indicates which entry is currently being addressed by the Pop Next Data Pointer, and RFCTR, in the same register, provides the number of entries stored in the RFIFO. Using POPNXTPTR and RFCTR, the absolute addresses for Pop Next Data Pointer and Receive Next Data Pointer can be calculated using the following formulas:

Pop Next Data Pointer Address = RFIFOx\_BASE\_ADDRESS + POPNXTPTRx\*4

Receive Next Data Pointer Address = RFIFOx\_BASE\_ADDRESS + [(POPNXTPTRx + RFCTRx) mod RFIFO\_DEPTH] \* 4

where

- $a \bmod b$  returns the remainder of the division of  $a$  by  $b$ .
- RFIFOx\_BASE\_ADDRESS is the smallest memory mapped address allocated to an RFIFOx entry.
- RFIFO\_DEPTH is the number of entries contained in a RFIFO - four in this implementation.

When a new message arrives and RFIFOx is not full, the EQADC copies its contents into the entry pointed by the Receive Next Data Pointer. The RFIFO counter RFCTRx in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) is incremented by one, and the Receive Next Data Pointer x is also incremented by one (or wrapped around) to

point to the next empty entry in RFIFOx. However, if the RFIFOx is full, the EQADC sets the RFOF in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#). The RFIFOx will not overwrite the older data in the RFIFO, the new data will be ignored, and the Receive Next Data Pointer x is not incremented or wrapped around. RFIFOx is full when the Receive Next Data Pointer x equals the Pop Next Data Pointer x and RFCTR<sub>x</sub> is not zero. RFIFOx is empty when the Receive Next Data Pointer x equals the Pop Next Data Pointer x and RFCTR<sub>x</sub> is zero.

When the EQADC RFIFO Pop Register x is read and the RFIFOx is not empty, the RFIFO counter RFCTR<sub>x</sub> is decremented by one, and the POP Next Data Pointer is incremented by one (or wrapped around) to point to the next RFIFO entry.

When the EQADC RFIFO Pop Register x is read and RFIFOx is empty, EQADC will not decrement the counter value and the POP Next Data Pointer x will not be updated. The read value will be undefined.

**Figure 29-136. RFIFO diagram**

The detailed behavior of the Pop Next Data Pointer and Receive Next Data Pointer is described in the example shown in [Figure 29-137](#) where an RFIFO with 16 entries is shown for clarity of explanation, the actual hardware implementation has only four entries. In this example, RFIFOx with 16 entries is shown in sequence after popping or receiving entries.

NOTE: x=0, 1, 2, 3, 4,

Figure 29-137. RFIFO entry pointer example

### 29.6.5.2 Distributing result data into RFIFOs

Data to be moved into the RFIFOs can come from different sources: from ADC0, from ADC1, or from the on-chip companion module through the PSI. All result data comes with the MESSAGE\_TAG / MESSAGE\_TAG2 field and the DEST / DEST2 field defining what should be done with the received data. The EQADC hardware decodes the MESSAGE\_TAG / MESSAGE\_TAG2 and DEST/DEST2 fields and:

- stores the 16-bit data into the appropriate RFIFO if the MESSAGE\_TAG / MESSAGE\_TAG2 indicates a valid RFIFO number, or;
- sends the 16-bit data, the MESSAGE\_TAG / MESSAGE\_TAG2 and the DEST / DEST2 data through the PSI to an on-chip companion module (as a decimation filter), or;
- ignores the data in case of a null or "reserved for customer use" MESSAGE\_TAG / MESSAGE\_TAG2.

In general received data is moved into RFIFOs as they become available, while an exception happens when multiple results from different sources become available at the same time. In that case, result data from ADC0 is processed first, result data from ADC1 is only processed after all ADC0 data is processed, and finally returned data from companion module is only processed after all data from ADC0/1 is processed.

When time-stamped results return from the on-chip ADCs, the conversion result and the time stamp are always moved to the RFIFOs in consecutive clock cycles in order to guarantee they are always stored in consecutive RFIFO entries.

## **29.6.6 On-chip ADC configuration and control**

### **29.6.6.1 Enabling and disabling the on-chip ADCs**

The on-chip ADCs have an enable bit (ADC0/1\_EN) in [ADC0/1 Control Registers \(ADC0\\_CR and ADC1\\_CR\)](#) that allows the enabling of the ADCs only when necessary. When the enable bit for an ADC is negated, the clock input to that ADC is stopped. The ADCs are disabled out of reset - ADC0/1\_EN bits are negated - to allow for their safe configuration. The ADC must only be configured when its enable bit is negated. Once the enable bit of an ADC is asserted, clock input to is started.

#### **Note**

Conversion commands sent to the CBuffer of a disabled ADC are ignored by the ADC control hardware.

#### **Note**

Due to legacy reasons, the EQADC will always wait 120 ADC clocks before issuing the first conversion command following the enabling of one of on-chip ADCs, or the exiting of stop mode. There are two independent counters checking for this delay: one clocked by ADC0\_CLK and another by

ADC1\_CLK. Conversion commands can start to be executed whenever one of these counters completes counting 120 ADC clocks.

### 29.6.6.2 ADC clock and conversion speed

The clock input to the ADCs is defined by setting the ADC0/1\_ODD\_PS, the ADC0/1\_CLK\_SEL and the ADC0/1\_CLK\_PS fields in [ADC0/1 Control Registers \(ADC0\\_CR and ADC1\\_CR\)](#). When the ADC0/1\_CLK\_SEL is set, the ADC clock frequency is the same as the system clock, but it has the inverted phase. When it is clear, the ADC0/1\_ODD\_PS and the ADC0/1\_CLK\_PS fields select the clock divide factor by which the system clock will be divided as shown in [Table 29-113](#). The ADC clock frequency is calculated as below and must not exceed ADC\_MAX\_CLOCK. This is also the maximum frequency of system clock when the ADC0/1\_CLK\_SEL is asserted.

$$\text{ADCClockFrequency} = \frac{\text{SystemClockFrequency(MHz)}}{\text{SystemClockDivideFactor}}$$

[Figure 29-138](#) depicts how the ADC clocks for ADC0 and ADC1 are generated.

**Figure 29-138. ADC0/1 clock generation**

The ADC conversion speed (in K samples per second: Ksps) is calculated by the following formula. The *number of sampling cycles* is determined by the LST bits in the command message—see [Conversion command format for the standard configuration](#)—

and can take one of the following values: 2, 8, 64, or 128 ADC clock cycles. The *number of AD conversion cycles* is 13 for differential conversions and 14 for single-ended 12-bit resolution and unitary input gain conversions. The maximum conversion speed is achieved when the ADC Clock frequency is set to its maximum and the number of sampling cycles set to its minimum (2 cycles). The maximum conversion speed is ADC\_MAX\_CONV\_RATE.

$$\text{ADCConversionSpeed} = \frac{\text{ADCClockFrequency(MHz)}}{(\text{NumberOfSamplingCycles} + \text{NumberOfADConversionCycles})}$$

Table 29-136 shows an example of how the ADC0/1\_CLK\_PS can be set when using a 120 MHz system clock and the corresponding conversion speeds for all possible ADC clock frequencies. The table also shows that according to the system clock frequency, certain clock divide factors are invalid (2, 4, 6, 8 clock divide factors in the example) because their use would result in a ADC clock frequency higher than the maximum one supported by the ADC. The ADC clock frequency must not exceed ADC\_MAX\_CLOCK.

**Table 29-136. ADC Clock configuration example (system clock frequency=120 MHz)**

| ADC0/1_CLK_PS<br>[0:4] | ADC0/1_ODD_PS | System clock<br>divide factor | ADC clock<br>(system clock =<br>120 MHz) | Differential<br>conversion speed<br>with default sampling<br>time (2 cycles) | Single-ended<br>conversion speed<br>with default sampling<br>time (2 cycles) |
|------------------------|---------------|-------------------------------|------------------------------------------|------------------------------------------------------------------------------|------------------------------------------------------------------------------|
| 0b00000                | 0             | 2                             | N/A                                      | N/A                                                                          | N/A                                                                          |

### 29.6.6.3 Time stamp feature

The on-chip ADCs can provide a time stamp for the conversions they execute. A time stamp is the value of the time base counter latched when the EQADC detects the end of the analog input voltage sampling. A time stamp for a conversion command is requested by setting the TSR bit in the corresponding command. When TSR is negated, that is a time stamp is not requested, the ADC returns a single result message containing the conversion result. When TSR is asserted, that is a time stamp is requested, the ADC returns two result messages; one containing the conversion result, and afterwards another containing the time stamp for that conversion. The result messages are sent in this order to the RFIFOs and both messages are sent to the same RFIFO was specified in the MESSAGE\_TAG field of the executed conversion command.

The time stamp can be provided by an external source using the STAC bus (more details in [STAC bus client sub-module \(STACC\)](#)) or by the internal time base counter. The selection between the two sources is done by field ADC0/1\_TBSEL in the ADC0/1\_CR register or by field ATBSEL in registers ADC\_ACR1-14. See [Table 29-112](#) and the ATBSEL field description in [Alternate Configuration 1-14 Control Registers \(ADC\\_ACR1-14\)](#) for selection details.

The time base counter is a 16-bit up counter that wraps after reaching 0xFFFF. It is disabled after reset and it is enabled according to the setting of TBC\_CLK\_PS field in [ADC Time Stamp Control Register \(ADC\\_TSCR\)](#). TBC\_CLK\_PS defines if the counter is enabled or disabled, and, if enabled, at what frequency it is incremented. The time stamps are returned regardless of whether the time base counter is enabled or disabled. The time base counter can be reset by writing 0x0000 to [ADC Time Base Counter Registers \(ADC\\_TBCR\)](#) with a write configuration command.

### 29.6.6.3.1 STAC bus client sub-module (STACC)

The STAC sub-block STACC extracts the external time base from the STAC bus to the EQADC. Figure 29-139 provides a block diagram for the STACC sub-module that contains actually two slot selectors.

**Figure 29-139. STAC bus client block diagram**

The STAC bus data stream is composed by several identified time slots. Each time slot contains a time value from a specified source. The bits SRV1/2[0:3] in register EQADC\_STACCR are used to select the desired time slots of the STAC bus to be used internally by the EQADC. Figure 29-140 shows a timing diagram for the STACC.

- NOTES: 1. Maximum of 16 Time Slots (TS[n])  
2. In this case, SRV bits were set to capture TS[01]

**Figure 29-140. Timing diagram for the STAC bus and STACC output**

Every time the selected time slot change, the STACC outputs are updated. As this time base is an external data to the EQADC, this output is not affected by the stop or by the debug internal state.

After the slot selection is done and the timebase data is extracted, the STACBS1/2 bits select 16 bits from the original 24-bit timebase data. These selected bits are the timebase to be used internal to the EQADC.

### 29.6.6.4 ADC pre-gain feature

Each ADC can be configured to have a selectable input gain as defined in [Alternate Configuration 1-14 Control Registers \(ADC\\_ACR1-14\)](#). This means the input signal is sampled and the result is amplified by factor 2, or 4 before the conversion phase. In present implementation of this feature, the conversion is 1 or 2 ADC clock cycles longer for gain 2 or gain 4, respectively.

### 29.6.6.5 ADC resolution selection feature

The ADCs conversion resolutions can be 8 bits, 10 bits or 12 bits as described in [Alternate Configuration 1-14 Control Registers \(ADC\\_ACR1-14\)](#). For conversions at a resolution less than 12, the ADC is executing less operations and the conversion time is smaller. In this ADC, it is verified that there is 1 ADC clock cycle for each bit of resolution. Therefore, for the same ADC clock frequency, the ADC sample frequency is higher for lower resolutions.

When a conversion is undertaken at a resolution less than 12, the result is presented by the ADC in right justified format in the 12-bit input bus e.g.: 0000xxxxxxx for 8 bits and 00xxxxxxxxxx for 10 bits. The EQADC inverts the result to left justified format i.e.: xxxxxxxx0000 for 8 bits and xxxxxxxxxx00 for 10 bits. This is because the same calibration coefficients in the MAC can then be used. The left shift operation is done just after the conversion result enters the EQADC, in the Resolution Adjustment block prior to the MAC, as illustrated in [Figure 29-143](#).

### 29.6.6.6 ADC calibration feature

#### 29.6.6.6.1 Overview

There are three sets of calibration coefficients for each ADC. Each set is composed by a gain factor and an offset factor: GCCn/OCCn, ALTGCCn1/ALTGCCn1, and ALTGCCn2/ALTGCCn2, where n is the ADC number 0 or 1. The pair GCCn/OCCn is selected when it is used the normal configuration or the alternate configurations 3 to 8. The pair ALTGCCn1/ALTGCCn1 is used only when the alternate configuration 1 is selected. And the pair ALTGCCn2/ALTGCCn2 is for the alternate configuration 2. The description below is for a generic pair of gain/offset GCC/OCC.

The EQADC provides a calibration scheme to remove the effects of gain and offset errors from the results generated by the on-chip ADCs. Only results generated by the on-chip ADCs are calibrated. The main component of calibration hardware is a Multiply-and-Accumulate (MAC) unit, one per on-chip ADC, that is used to calculate the following transfer function which relates a calibrated result to a raw, uncalibrated one.

$$\text{CAL\_RES} = \text{GCC} * \text{RAW\_RES} + \text{OCC} + 2;$$

where:

- CAL\_RES is the calibrated result corresponding the input voltage  $V_i$ .
- GCC is the gain calibration constant.
- RAW\_RES is the raw, uncalibrated result with resolution adjustment corresponding to an specific input voltage  $V_i$ .
- OCC is the offset calibration constant.
- The addition of two reduces the maximum quantization error of the ADC. See [Quantization error reduction during calibration](#).

Calibration constants GCC and OCC are determined by taking two samples of known reference voltages and using these samples to calculate the values for the constants. For details and an example about how to calculate the calibration constants and use them in result calibration see [ADC Result Calibration](#). Once calculated, GCC is stored in [ADC0/1 Gain Calibration Constant Registers \(ADC0\\_GCCR and ADC1\\_GCCR\)](#) and OCC in [ADC0/1 Offset Calibration Constant Registers \(ADC0\\_OCCR and ADC1\\_OCCR\)](#), from where their values are fed to the MAC unit. The alternate gain values are stored in [ADC0/1 Alternate Gain Registers \(ADC0\\_AGR1-2 and ADC1\\_AGR1-2\)](#) and the alternate offset values in [ADC0/1 Alternate Offset Register \(ADC0\\_AOR1-2 and ADC1\\_AOR1-2\)](#). Since the analog characteristics of each on-chip ADCs differs, each ADC has an independent pair of calibration constants.

A conversion result is calibrated according to the status of CAL bit in the command that initiated the conversion. If the CAL bit is asserted, the EQADC will automatically calculate the calibrated result before sending the result to the appropriate RFIFO or companion module. If the CAL bit is negated, the result is not calibrated, it bypasses the calibration hardware, and is directly sent to the appropriate RFIFO or companion module.

#### 29.6.6.6.2 MAC unit and operand data format

The MAC unit diagram is shown in [Figure 29-141](#). Each on-chip ADC has a separate MAC unit to fine-tune its conversion results. The description below considers the general calibration constant registers but it is the same for the alternate calibration constants.

The OCC0/1 operand is a 14-bit signed value stored in [ADC0/1 Offset Calibration Constant Registers \(ADC0\\_OCCR and ADC1\\_OCCR\)](#)." The RAW\_RES operand is the raw uncalibrated result, and it is the direct output from the on-chip ADCs but passing through the resolution adjustment block. The GCC0/1 operand is a 15-bit fixed point unsigned value stored in [ADC0/1 Gain Calibration Constant Registers \(ADC0\\_GCCR and ADC1\\_GCCR\)](#)." The GCC is expressed in the *GCC\_INT.GCC\_FRAC* binary format. The integer part of the GCC (GCC\_INT=GCC[1]) contains a single binary digit while its fractional part (GCC\_FRAC=GCC[2:15]) contains 14 bits - see [Figure 29-142](#). The gain constant equivalent decimal value ranges from 0 to 1.999938..., as shown in [Table 29-138](#). Two is always added to the MAC output - see [Quantization error reduction during calibration](#). CAL\_RES output is the calibrated result, and it is a 14-bit unsigned value. CAL\_RES is truncated to 0x3FFF, in case of a overflow, and to 0x0000, in case of an underflow.

### 29.6.6.7 ADC control logic overview and command execution

Figure 29-143 shows the basic logic blocks involved in the ADC Control and how they interact. CFIFOs/RFIFOs interact with CBuffers/*Abort Cont/Result Message Return Logic* through the *FIFO Control Unit*. The EB and BN bits in the Command Message uniquely identify the CBuffer to which a command should be sent. The *FIFO Control Unit* decodes these bits and sends the ADC command to the proper CBuffer. Other blocks of logic are the *Resolution Adjustment*, *Result Format and Calibration Sub-Block*, the *Time Stamp Logic*, and the *MUX Control Logic*.

The *Resolution Adjustment Sub-Block* receives the 12-bit data bus directly from the ADC and changes the received conversion results from right aligned format of ADC to the left aligned format depending on the selected resolution of the conversion. This operation helps the calibration processing to use the calibration coefficients always with the same format.

The *Result Format and Calibration Sub-Block* formats the returning data into Result Messages and sends them to the RFIFOs <sup>6</sup>. The returning data can be data read from an ADC register, a conversion result, or a time stamp. The formatting and calibration of conversion results also take place inside this sub-block.

The *Time Stamp Logic* latches the value of the time base counter or the STAC bus time base when detecting the end of the analog input voltage sampling, and sends it to the *Result Format and Calibration Sub-Block* as time stamp information.

The *MUX Control Logic* generates the proper MUX control signals and, when the ADC0/1\_EMUX bits are asserted, the MA signals based on the channel numbers extracted from the ADC Command.

When the on-chip ADC abort feature is not enabled, ADC Commands are stored in the CBuffers as they come and they are executed in the first-in-first-out basis. After the execution of a command in ENTRY1 finishes all commands are shifted one entry. After the shift, ENTRY0 is always empty and ready to receive a new command. Execution of configuration commands only start when they reach ENTRY1. Consecutive conversion commands are pipelined and their execution can start while in ENTRY0. This is explained below.

AD conversion accuracy can be affected by the settling time of the input channel multiplexers. Some time is required for the channel multiplexers internal capacitances to settle after the channel number is changed. If the time prior to sampling is not long enough to absorb this settling, then the settling time will take from ADC sampling time which may result in inaccurate sampling and ultimately compromise conversion result accuracy - see [Figure 29-144](#) (a). This could be avoided by switching the multiplexers in preparation for the next command's sampling during the AD conversion phase of the current command as showed in [Figure 29-144](#) (b). In EQADC, this is done in the following way; when a conversion command is in buffer ENTRY1 and another conversion command is identified in ENTRY0, then the channel number of ENTRY0 is sent to the *MUX Control Logic* some cycles before the sampling phase of the command in ENTRY0 starts. In this way, sampling for the next command can promptly start after the current conversion finishes because the internal capacitance of the multiplexers will be settled by that time, allowing for more accurate sampling. This is specially important for applications that require high conversion speeds, that is with the ADC running at maximum clock frequency and with the analog input voltage sampling time set to a minimum (2 ADC clock cycles), when the short sampling time does not allow the multiplexers to completely settle. The second advantage of pipelining conversion

6. The result messages may also be routed to an on-chip companion module via the side interface, and then fed back to the RFIFOs.

commands is to provide precise conversion intervals, which means the time intervals between two consecutive conversions are the same. This is important for any digital signal process application.

When the on-chip ADC abort feature is enabled, ADC Commands from CFIFO0 should be considered immediately, even stopping the execution of some command that is already in ENTRY1. When the abort request is sent to the ADC, the already stored commands in the CBuffers are copied in a temporary set of registers. The first ADC command from CFIFO0 is sent after the abort acknowledge indication from ADC. The process is the same as usual until the transfer of the last command from CFIFO0. Then the temporarily stored commands that were postponed by the abortion are recovered and they are pipelined for execution. After the last command from this temporary memory is transferred, the next commands are pipelined from the CFIFOs.

## 29.6.7 Internal/external multiplexing

### 29.6.7.1 Channel assignment

The internal analog multiplexers select one of the 40 analog input pins for conversion, based on the CHANNEL\_NUMBER field of a Command Message. The analog input pin channel number assignments and the pin definitions vary depending on how the ADC0/1\_EMUX are configured. Allowed combinations of ADC0/1\_EMUX bits are shown in [Table 29-139](#) together with references to tables indicating how CHANNEL\_NUMBER field of each conversion command must be set to avoid channel selection conflicts.

During differential conversions the analog multiplexer passes differential signals to both the positive and negative terminals of the ADC. The differential conversions can only be initiated on four channels: DAN0, DAN1, DAN2, and DAN3. See chip-specific section for the channel numbers used to select differential conversions.

**Table 29-139. ADC0/1\_EMUX bits combinations**

| ADC0_EMUX | ADC1_EMUX | CHANNEL_NUMBER should be set as in    |                                       |
|-----------|-----------|---------------------------------------|---------------------------------------|
|           |           | ADC0                                  | ADC1                                  |
| 0         | 0         | See chip-specific section for details | See chip-specific section for details |
| 0         | 1         | See chip-specific section for details | See chip-specific section for details |
| 1         | 0         | See chip-specific section for details | See chip-specific section for details |
| 1         | 1         | Reserved <sup>1</sup>                 |                                       |

1. ADC0\_EMUX and ADC1\_EMUX must not be asserted at the same time

See the chip-specific EQADC information for channel number assignments for the non-multiplexed mode. The two on-chip ADCs can access the same analog input pins but simultaneous conversions are not allowed. Also, when one ADC is performing a differential conversion on a pair of pins, the other ADC must not access either of these two pins as single-ended channels. The 43 single-ended channels and 4 differential pairs are shared between the two ADCs.

See the chip-specific EQADC information for the channel number assignments for multiplexed mode. The two on-chip ADCs can access the same analog input pins but simultaneous conversions are not allowed. Also, when one ADC is performing a differential conversion on a pair of pins, the other ADC must not access either of these two pins as single-ended channels. The ADC with the ADC0/1\_EMUX bit asserted can access 4 differential pairs, 39 single-ended, and, at most, 64 externally multiplexed channels. See [External multiplexing](#) for a detailed explanation about how external multiplexing can be achieved.

### 29.6.7.2 External multiplexing

The EQADC can use from one to eight external multiplexer chips to expand the number of analog signals that may be converted. Up to 64 analog channels can be converted through external multiplexer selection. The externally multiplexed channels are automatically selected by the CHANNEL\_NUMBER field of a Command Message, in the same way done with internally multiplexed channels. The software selects the external multiplexed mode by setting the ADC0/1\_EMUX bit in either ADC0\_CR or ADC1\_CR depending on which ADC will perform the conversion. See the chip-specific EQADC information for the channel number assignments for the multiplexed mode.

There are 4 differential pairs, 39 single-ended, and, at most, 64 externally multiplexed channels which can be selected. Only one ADC can have its ADC0/1\_EMUX bit asserted at a time.

Figure 29-145 shows the maximum configuration of eight external multiplexer chips connected to the EQADC. The external multiplexer chip selects one of eight analog inputs and connects it to a single analog output, which is fed to a specific input of the EQADC. The EQADC provides three multiplexed address signals, MA0, MA1, and MA2, to select one of eight inputs. These three multiplexed address signals are connected to all eight external multiplexer chips. The analog output of the eight multiplex chips are each connected to eight separate EQADC inputs, ANR, ANS, ANT, ANU, ANW, ANX, ANY, and ANZ. The MA pins correspond to the three least significant bits of the channel number that selects ANR, ANS, ANT, ANU, ANW, ANX, ANY, and ANZ with MA0 being the most significant bit - See Table 29-140. In that table, '0' means pin is driven LOW and '1' that pin is driven HIGH.

**Table 29-140. Encoding of MA pins**

| Channel number selecting ANR, ANS, ANT, ANU, ANW, ANX, ANY, ANZ (decimal) |     |     |     |     |     |     |     | MA0 | MA1 | MA2 |
|---------------------------------------------------------------------------|-----|-----|-----|-----|-----|-----|-----|-----|-----|-----|
| ANR                                                                       | ANS | ANT | ANU | ANW | ANX | ANY | ANZ |     |     |     |
| 224                                                                       | 232 | 240 | 248 | 64  | 72  | 80  | 88  | 0   | 0   | 0   |
| 225                                                                       | 233 | 241 | 249 | 65  | 73  | 81  | 89  | 0   | 0   | 1   |
| 226                                                                       | 234 | 242 | 250 | 66  | 74  | 82  | 90  | 0   | 1   | 0   |
| 227                                                                       | 235 | 243 | 251 | 67  | 75  | 83  | 91  | 0   | 1   | 1   |
| 228                                                                       | 236 | 244 | 252 | 68  | 76  | 84  | 92  | 1   | 0   | 0   |
| 229                                                                       | 237 | 245 | 253 | 69  | 77  | 85  | 93  | 1   | 0   | 1   |
| 230                                                                       | 238 | 246 | 254 | 70  | 78  | 86  | 94  | 1   | 1   | 0   |
| 231                                                                       | 239 | 247 | 255 | 71  | 79  | 87  | 95  | 1   | 1   | 1   |

When the external multiplexed mode is selected for either ADC, the EQADC automatically creates the MA output signals from CHANNEL\_NUMBER field of a Command Message. The EQADC also converts the proper input channel (ANR, ANS, ANT, ANU, ANW, ANX, ANY, and ANZ) by interpreting the CHANNEL\_NUMBER field. As a result, up to 64 externally multiplexed channels appear to the conversion queues as directly connected signals.

Figure 29-145. Example of external multiplexing

## 29.6.8 EQADC DMA/interrupt request

Table 29-141 lists methods to generate interrupt requests in the EQADC queuing control and triggering control. The DMA/interrupt request select bits and the DMA/interrupt enable bits are described in [EQADC Interrupt and DMA Control Register 0 \(EQADC\\_IDCR0\)](#) and the interrupt flag bits are described in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#). Figure 29-146 depicts all interrupts and DMA requests generated by the EQADC. For details, see [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) and [EQADC Interrupt and DMA Control Register 0 \(EQADC\\_IDCR0\)](#).

**Table 29-141. EQADC FIFO interrupt summary**

| Interrupt                                     | Condition                                                               | Clearing mechanism                                       |
|-----------------------------------------------|-------------------------------------------------------------------------|----------------------------------------------------------|
| Non Coherency Interrupt                       | NClEx = 1<br>NCFx = 1                                                   | Clear NCFx bit by writing a "1" to the bit.              |
| Result FIFO Overflow Interrupt <sup>1</sup>   | RFOlEx = 1<br>RFOF <sub>x</sub> = 1                                     | Clear RFOF <sub>x</sub> bit by writing a "1" to the bit. |
| Command FIFO Underflow Interrupt <sup>1</sup> | CFUIEx = 1<br>CFUF <sub>x</sub> = 1                                     | Clear CFUF <sub>x</sub> bit by writing a "1" to the bit. |
| Result FIFO Drain Interrupt                   | RFDE <sub>x</sub> = 1<br>RFDS <sub>x</sub> = 0<br>RFDF <sub>x</sub> = 1 | Clear RFDF <sub>x</sub> bit by writing a "1" to the bit. |
| Command FIFO Fill Interrupt                   | CFFEx = 1<br>CFFS <sub>x</sub> = 0<br>CFFF <sub>x</sub> = 1             | Clear CFFF <sub>x</sub> bit by writing a "1" to the bit. |
| End of Queue Interrupt                        | EOQlEx = 1<br>EOQF <sub>x</sub> = 1                                     | Clear EOQF <sub>x</sub> bit by writing a "1" to the bit. |
| Pause Interrupt                               | PIEx = 1<br>PF <sub>x</sub> = 1                                         | Clear PF <sub>x</sub> bit by writing a "1" to the bit.   |
| Trigger Overrun Interrupt <sup>1</sup>        | TORlEx = 1<br>TORF <sub>x</sub> = 1                                     | Clear TORF <sub>x</sub> bit by writing a "1" to the bit. |

1. Apart from generating an independent interrupt request for when a RFIFO Overflow Interrupt, a CFIFO Underflow Interrupt, and a CFIFO Trigger Overrun Interrupt occurs, the EQADC also provides a combined interrupt request at which these requests from ALL CFIFOs are ORed. Refer to [Figure 1](#) for details.

Table 29-142 describes a list of methods to generate DMA requests in the EQADC. For details, see [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#) and [EQADC Interrupt and DMA Control Register 0 \(EQADC\\_IDCR0\)](#).

**Table 29-142. EQADC FIFO DMA Summary**

| DMA Request                                   | Condition                           | Clearing Mechanism                                                                                               |
|-----------------------------------------------|-------------------------------------|------------------------------------------------------------------------------------------------------------------|
| Result FIFO Drain DMA <sup>1</sup><br>Request | RFDEx = 1<br>RFDSx = 1<br>RFDFx = 1 | The EQADC automatically clears the RFDFx when RFIFOx becomes empty. Writing "1" to the RFDFx bit is not allowed. |
| Command FIFO Fill DMA<br>Request              | CFFEx = 1<br>CFFSx = 1<br>CFFFx = 1 | The EQADC automatically clears the CFFFx when CFIFOx becomes full. Writing "1" to the CFFFx bit is not allowed.  |

1. Additional readings from RFIFOx (not from DMA control) can clear the RFDFx bit and can lock the DMAx circuit to a locked state. The DMAx request remains ON, despite RFDFx is cleared.

Figure 29-146. EQADC DMA and interrupt requests

## 29.6.9 EQADC Parallel Side Interface (PSI) sub-block

**Figure 29-147. EQADC Parallel Side Interface block diagram**

The EQADC PSI sub-block allows communication between the EQADC and the companion modules through a local slave bus that has the EQADC block as the master and the companion modules as the slaves. However, due to implementation constraints, a limited number of addresses is defined and a maximum of 15 different slave blocks to be enabled.

The conversion result goes through the Result Formatting and Calibration sub-block and the corresponding MESSAGE\_TAG / MESSAGE\_TAG2 and DEST/DEST2 fields are decoded to decide the destination of the conversion result data. When the DEST field is not zero as described in [Alternate Configuration 1-14 Control Registers \(ADC\\_ACR1-14\)](#), the MESSAGE\_TAG bits, control bits, and the conversion result data are sent to the transmission section of the PSI sub-block. This set of data is processed and sent to the corresponding on-chip companion module.

The configuration bit DAM is described in [EQADC Module Configuration Register \(EQADC\\_MCR\)](#). The DEST2/MESSAGE\_TAG2 fields are only used as defined in [Extended Alternate Configuration 1-14 Control Registers \(ADC\\_EACR1-14\)](#) when

DAM=1. DAM bit selects between two different "tap modes", each defining a different way to select the second destination. When DAM=0 the DEST field can set the transmission section to send the same result data / MESSAGE\_TAG to two destinations. See [Table 29-120](#) in [Alternate Configuration 1-14 Control Registers \(ADC\\_ACR1-14\)](#). When DAM=1, the two destinations are selected as described in [Table 29-124](#).

The companion module can also send back to EQADC the result of some processing in the received data. In this case, the receiver section of the PSI sub-block treats this request and receives the result data with the corresponding MESSAGE\_TAG or TAG field. This TAG is used by the decoder to select which RFIFO will be written with the received companion module data.

A companion module with two PSIs can be connected to two EQADCs. For this case, there is the bit field RPSI described in [Alternate Configuration 1-14 Control Registers \(ADC\\_ACR1-14\)](#) and the bit field RPSI2 described in [Alternate Configuration 1-14 Control Registers \(ADC\\_ACR1-14\)](#) that control the routing of the companion module output result to any PSI.

### 29.6.9.1 Input / output signals description

The information content of the input and the output data buses from/to the companion modules are described in [Figure 29-148](#). The input data format is used in the Read cycle and corresponds to the data supplied by some companion module. The output data format is used in the Write cycle of this interface block and contains information / controls to some companion module.

## On-chip ADC configuration and control

Read (Input) / Write (Output) Data Buses Content

**Table 29-143. PSI input and output data buses content — field descriptions (continued)**

| Field                 | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|-----------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                       | <p>01 CONVERSION RESULT - It indicates that the ADC_CONV_RESULT field should be treated as a valid sample data. This control mode is useful to Decimation Filter to put the filter em normal mode instead of prefill mode.</p> <p>10 TIME STAMP o REGISTER READ - A time stamp indicates that the ADC_CONV_RESULT field should follow a bypass flow in the companion module, returning back to the EQADC without any modification.</p> <p>11 Reserved</p>                                                                                                                                                                                            |
| MESSAGE_TAG[0:3]      | <p>Message tag bits field</p> <p>This field indicates the RFIFO destination associated with the ADC_CONV_RESULT sample. This value is stored by the companion module and is used to address the destination RFIFO register when a RESULT_DATA is generated due to that ADC_CONV_RESULT sample.</p> <p><b>Note:</b> In case the companion module only receives data from eQADC and does not return any result to eQADC RFIFOs, the MESSAGE_TAG field can be used as a destination router in the companion module. The eQADC module can send conversion results to sub-blocks in the companion module that are addressed by the MESSAGE_TAG value.</p> |
| TAG[0:3]              | <p>Companion module tag bits</p> <p>This bit field is used to address the appropriate destination RFIFO in the EQADC for the accompanying RESULT_DATA bits. However, it can be used too in the companion module to select the destination of the conversion result data.</p> <p>In eQADC application, this is used to address the appropriate RFIFO in the eQADC block. In this case, the possible values are only from 0000 to 0101.</p>                                                                                                                                                                                                            |
| ADC_CONV_RESULT[0:15] | <p>ADC Conversion Result Data</p> <p>This bit field is the ADC conversion result data after passing through the calibration and formatting block.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| RESULT_DATA[0:15]     | <p>Companion Module Result Data</p> <p>This bit field corresponds to the companion module data processing result to EQADC.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

### 29.6.9.2 PSI Transmitter / Write Section

The transmission sub-block formats the data bus from RFIFO control sub-block to send to the PSI slave wdata bus. The transmission data is registered and its content is described in [Input / output signals description](#). The transmission has higher priority than reception. This is done to avoid the use of memory to store transmission data and it is not used waiting time for transmission.

The destination companion module for the transmission data is obtained by decoding the DEST[0:3] and DEST2 bits. The not null decimal value of DEST[0:3] or DEST2 is used to set one or two corresponding module enable signals as already described. For example, DEST[0:3] value equal to 0x1 that corresponds to the decimal value 1 is going to set only the module enable 1. All other module enable from 2 to 15 are not set due to DEST.

However, using the DEST2 value there are cases that two module enables are set, as described in [Table 29-120](#) in [Alternate Configuration 1-14 Control Registers \(ADC\\_ACR1-14\)](#).

### **29.6.9.3 PSI Receiver / Read Section**

The receiver sub-block receives data from some companion module using the PSI slave bus interface. The companion module sends a read request to EQADC using the DMA read request line. The PSI logic sends a read command if there is no transmission request. The received data has the structure described in [Input / output signals description](#).

The receiver section can receive read request from several companion modules at the same time. A prioritization scheme is used to decide which request should be served first. The request with lower index has higher priority.

#### **Note**

In case of receiving data (D1, D2) and timestamp (T1, T2) from two companion modules with the same TAG at almost the same time, the RFIFOx can receive the pair data/timestamp out of order due to the present prioritization logic in the PSI receiver. An expected sequence (D1 T1 D2 T2) can be changed to (D1 D2 T2 T1) if D2/T2 has higher priority than T2. [Table 29-124](#) presents some cases that presents this inversion.

## **29.6.10 Analog sub-block**

### **29.6.10.1 Analog to digital converter (ADC)**

#### **29.6.10.1.1 ADC architecture**

**Figure 29-149. RSD ADC block diagram**

The RSD Cyclic ADC consists of two main portions, the analog RSD Stage, and the digital control and calculation block, as shown in [Figure 29-149](#). To begin an analog to digital conversion, a differential input is passed into the analog RSD stage. The signal is passed through the RSD stage, and then from the RSD stage output, back to its input to be passed again. To complete a 12-bit conversion, the signal must pass through the RSD stage 12 times. For 10-bit and 8-bit resolution, the signal must pass 10 or 8 times through the RSD. Each time an input signal is read into the RSD stage, a digital sample is taken by the digital control/calculation block. The digital control/calculation block uses this sample to tell the analog block how to condition the signal. The digital block also saves each successive sample and adds them according to the RSD algorithm at the end of the entire conversion cycle.

#### 29.6.10.1.2 RSD Overview

**Figure 29-150. RSD stage block diagram**

On each pass through the RSD stage, the input signal will be multiplied by exactly two, and summed with either  $-V_{REF}$ , 0, or  $V_{REF}$ , depending on the Logic Control. The Logic Control will determine  $-V_{REF}$ , 0, or  $V_{REF}$  depending on the two comparator inputs. As the Logic Control sets the summing operation, it also sends a digital value to the RSD adder. Each time an analog signal passes through the RSD single-stage, a digital value is collected by the RSD adder. At the end of an entire AD conversion cycle, the RSD adder uses these collected values to calculate the 12-bit/10-bit/8-bit digital output.

[Figure 29-151](#) shows the transfer function for the RSD stage. Note how the digital value (a, b) is dependent on the two comparator inputs.

**Figure 29-151. RSD Stage Transfer Function**

In each pass through the RSD stage, the residue will be sent back to be the new input, and the digital signals, *a* and *b*, will be stored. For the 12-bit ADC, input signal is sampled during the input phase, and after each of the 12 passes through the RSD stage. Thus, 13 total *a* and *b* values are collected. Upon collecting all these values, they will be added according to the RSD algorithm to create the 12-bit digital representation of the original analog input. The bits are added in the following manner:

#### 29.6.10.1.3 RSD adder

The array, *s1* to *s12*, will be the digital output of the RSD ADC with *s1* being the MSB and *s12* being the LSB.

Figure 29-152. RSD adder

#### 29.6.10.1.4 Variable Gain Amplification (VGA) for pre-gain

The VGA starts after sampling completes. It is enabled by a 2-bit signal `PRE_GAIN` described in [Alternate Configuration 1-14 Control Registers \(ADC\\_ACR1-14\)](#).

The ADC takes 2, 8, 64 or 128 clock cycles to do sampling which is selected by the `LST[0:1]` field in the conversion command message. After the sampling, if 2x VGA is enabled, there is a 2x gain stage without comparison before the regular conversion cycles. When 4x VGA is enabled, there are the 2x gain stage without comparison by 2 times before the normal conversion processing.

## 29.7 Initialization/application information

### 29.7.1 Multiple queues control setup example

This section provides an example of how to configure multiple CQueues. [Table 29-144](#) describes how each CQueue can be used for a different application. Also documented in this section are general guidelines on how to initialize the on-chip ADCs and how to configure the CQueues and the EQADC.

Table 29-144. Application of each CQueue

| CQueue number | CQueue type                       | Running speed                                                          | Number of contiguous conversions | Example                                     |
|---------------|-----------------------------------|------------------------------------------------------------------------|----------------------------------|---------------------------------------------|
| 0             | Very fast burst time-based CQueue | every 2 $\mu$ s for 200 $\mu$ s; pause for 300 $\mu$ s and then repeat | 2                                | Injector current profiling                  |
| 1             | Fast hardware-triggered CQueue    | every 900 $\mu$ s                                                      | 3                                | Current sensing of PWM controlled actuators |

Table continues on the next page...

**Table 29-144. Application of each CQueue (continued)**

| CQueue number | CQueue type                       | Running speed     | Number of contiguous conversions | Example                                   |
|---------------|-----------------------------------|-------------------|----------------------------------|-------------------------------------------|
| 2             | Fast repetitive time-based CQueue | every 2 ms        | 8                                | Throttle position                         |
| 3             | Software-triggered CQueue         | every 3.9 ms      | 3                                | Command triggered by software strategy    |
| 4             | Repetitive angle-based CQueue     | every 625 $\mu$ s | 7                                | Airflow read every 30 degrees at 8000 RPM |
| 5             | Slow repetitive time-based CQueue | every 100 ms      | 10                               | Temperature sensors                       |

### 29.7.1.1 EQADC initialization

The following steps provide an example about how to configure the EQADC controls and how to initialize the on-chip ADCs. In this example, all conversion commands will be transferred through CFIFO0.

1. Load all required configuration commands in the RAM in such way that they form a queue; this data structure will be referred below as CQueue0. [Figure 29-153](#) shows an example of a CQueue able to configure the on-chip ADCs. Although, this example uses the DMAC to store commands in CFIFO0, configuration commands could have also been directly written to the CFIFO0 push register.
2. Select source driving EQADC hardware trigger ports (ETRIG). Before proceeding to next step, allow some time (minimum of two system clocks - filter period is set to minimum after reset) so that the logic level at the source is filtered and reaches the EQADC control logic.

#### Note

ETRIG ports could be driven by an external pin or by the output port of other blocks in the device, such as timers. In order to avoid unexpected triggering of CFIFOs in hardware trigger modes, the source driving the ETRIG port must be selected and set to a known logic level before putting the CFIFOs into the WAITING FOR TRIGGER state.

The trigger filter bypass control inputs must be set considering the characteristics of the trigger signal. A particular case to assert the bypass control is when a device's internal signal with one clock width pulse is used.

- 3. Configure [EQADC External Trigger Digital Filter Register \(EQADC\\_ETDFR\)](#).
- 4. Configure the DMAC to transfer data from CQueue0 to CFIFO0 in the EQADC.
- 5. Configure [EQADC Interrupt and DMA Control Register 0 \(EQADC\\_IDCR0\)](#).
  - Set CFFS0 to configure the EQADC to generate a DMA request to load commands from CQueue 0 to the CFIFO0.
  - Set CFFE0 to enable the EQADC to generate a DMA request to transfer commands from CQueue0 to CFIFO0; Command transfers from the RAM to the CFIFO0 will start immediately.
  - Set EOQIE0 to enable the EQADC to generate an interrupt after transferring all of the commands of CQueue0 through CFIFO0.
- 6. Configure [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#).
  - Write 0b0001 to the MODE0 field in EQADC\_CFCR0 to program CFIFO0 for software single-scan mode.
  - Write "1" to SSE0 to assert SSS0 and trigger CFIFO0.
- 7. Since CFIFO0 is in single-scan software mode and it is also the highest priority CFIFO, the EQADC starts to transfer configuration commands to the on-chip ADCs.
- 8. When all of the configuration commands have been transferred, CF0 in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISRn\)](#) will be set. The EQADC generates a End of Queue interrupt. The initialization procedure is complete.

Figure 29-153. Example of a CQueue configuring the on-chip ADCs

The initialization procedure described above does not generate ADC clocks that are in phase because the timing at which the ADC0/1\_EN bits, in [ADC0/1 Control Registers \(ADC0\\_CR and ADC1\\_CR\)](#), are set is different. Below follows an example on how to simultaneously set these bits so that in-phase ADC clocks are generated. In this example, ADC0/1\_CLK are configured to the same frequency.

1. Push an ADC0\_CR write configuration command in CFIFO0 that enables ADC0 (ADC0\_EN=1) and that sets the ADC0\_CLK\_PS to an appropriate value. For example, 0x80800801.
2. Push an ADC1\_CR write configuration command in CFIFO1 that enables ADC1 (ADC1\_EN=1) and that sets the ADC1\_CLK\_PS to an appropriate value. For example, 0x82800801.
3. Configure CFIFO0 and CFIFO1 to single scan software trigger mode and simultaneously trigger them by writing 0x04100410 to the EQADC\_CFCR0 register - see [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#).

### 29.7.1.2 Configuring EQADC for applications

This section provides an example based on the applications in [Table 29-144](#). The example describes how to configure multiple CQueues to be used for those applications and provides a step-by-step procedure to configure the EQADC and the associated CQueue structures. In the example, the "Fast hardware-triggered CQueue", described on the second row of [Table 29-144](#), will have its commands transferred to CBuffer1; the conversion commands will be executed by ADC1. The generated results will be returned to RFIFO3 before being transferred to the RQueues in the RAM by the DMAC.

#### Note

There is no fixed relationship between CFIFOs and RFIFOs with the same number. The results of commands being transferred through CFIFO1 can be returned to any RFIFO, regardless of its number. The destination of a result is determined by the MESSAGE\_TAG field of the command that requested the result. See [Message format in EQADC](#) for details.

Step One: Setup the CQueues and RQueues.

1. Load the RAM with configuration and conversion commands. [Figure 29-154](#) is an example of how CQueue1 commands should be set.

- Each trigger event will cause four commands to be executed. When the EQADC detects the Pause bit asserted, it will wait for another trigger to restart transferring commands from the CFIFO.
- At the end of the CQueue, the "EOQ" bit is asserted as shown in [Figure 29-154](#).
- Results will be returned to RFIFO3 as specified in the MESSAGE\_TAG field of commands.

## 2. Reserve memory space for storing results.

| Bit Name     | 0  | 1     | 2   | 3        | 4  | 5  | 6        | 7                   | 8                                                        | 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 | 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28 | 29 | 30 | 31 |

| CMD 1        | 0  | 0     | 0   | 0        | 0  | 1  | 0        | 0b0011              | Conversion Command                                       |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| CMD 2        | 0  | 0     | 0   | 0        | 0  | 1  | 0        | 0b0011              | Conversion Command                                       |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| CMD 3        | 0  | 0     | 0   | 0        | 0  | 1  | 0        | 0b0011              | Conversion Command                                       |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| CMD 4        | 0  | 1     | 0   | 0        | 0  | 1  | 0        | 0b0011 <sup>1</sup> | Configure peripheral device for next conversion sequence |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| CMD 5        | 0  | 0     | 0   | 0        | 0  | 1  | 0        | 0b0011              | Conversion Command                                       |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| CMD 6        | 0  | 0     | 0   | 0        | 0  | 1  | 0        | 0b0011              | Conversion Command                                       |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| CMD 7        | 0  | 0     | 0   | 0        | 0  | 1  | 0        | 0b0011              | Conversion Command                                       |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| CMD 8        | 0  | 1     | 0   | 0        | 0  | 1  | 0        | 0b0011 <sup>1</sup> | Configure peripheral device for next conversion sequence |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
|              |    |       |     | 0        |    |    |          |                     | etc. ....                                                |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| CMD EQ       | 1  | 0     | 0   | 0        | 0  | 1  | 0        | 0b0011              | EOQ Message                                              |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| CFIFO Header |    |       |     |          |    |    |          |                     | ADC Command                                              |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |

Fields LST, TSR, FMT, and CHANNEL\_NUMBER are not showed for clarity.

<sup>1</sup> MESSAGE\_TAG field is only defined for read configuration commands.

**Figure 29-154. Example of CQueue commands**

Step Two: Configure the DMAC to handle data transfers between the CQueues/RQueues in RAM and the CFIFOs/RFIFOs in the EQADC.

1. For transferring, set the source address of the DMAC to point to the start address of CQueue1. Set the destination address of the DMAC to point to EQADC\_CFPR1. See [EQADC CFIFO Push Register \(EQADC\\_CFPRn\)](#).
2. For receiving, set the source address of the DMAC to point to EQADC\_RFPR3. See [EQADC Result FIFO Pop Register \(EQADC\\_RFPRn\)](#). Set the destination address of the DMAC to point to the starting address of RQueue1.

Step Three: Configure the EQADC Control Registers.

3. Configure [EQADC Interrupt and DMA Control Register 0 \(EQADC\\_IDCR0\)](#).
  - Set EOQIE1 to enable the End of Queue Interrupt request.
  - Set CFFS1 and RFDS3 to configure the EQADC to generate DMA requests to push commands into CFIFO1 and to pop result data from RFIFO3.
  - Set CFINV1 to invalidate the contents of CFIFO1.
  - Set RFDE3 and CFFE1 to enable the EQADC to generate DMA requests. Command transfers from the RAM to the CFIFO1 will start immediately.
  - Set RFOIE3 to indicate if RFIFO3 overflows.
  - Set CFUIE1 to indicate if CFIFO1 underflows.
4. Configure MODE1 to continuous-scan rising edge external trigger mode in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#).

Step Four: Command transfer to ADCs and Result data reception.

When an external rising edge event occurs for CFIFO1, the EQADC automatically will begin transferring commands from CFIFO1 when it becomes the highest priority CFIFO trying to send commands to CBuffer1. The received results will be placed in RFIFO3 and then moved to RQueue1 by the DMAC.

## 29.7.2 EQADC/DMAC interface

This section provides an overview about the EQADC/DMAC interface and general guidelines about how the DMAC should be configured in order for it to correctly transfer data between the queues in system memory and the EQADC FIFOs.

### Note

Advanced DMACs provide more functionality than the ones discussed in this section.

### 29.7.2.1 CQueue/CFIFO transfers

In transfers involving CQueues and CFIFOs, the DMAC moves data from a queued source to a single destination as showed in [Figure 29-155](#). The location of the data to be moved is indicated by the source address, and the final destination for that data, by the destination address. The DMAC contains a data structure containing these addresses and other parameters used in the control of data transfers. For every DMA request issued by the EQADC, the DMAC has to be configured to transfer a single command (32-bit data) from the CQueue, pointed to by the source address, to the CFIFO push register, pointed to by the destination address. After the service of a DMA request is completed, the source address has to be updated to point to the next valid command. The destination address remains unchanged. When the last command of a queue is transferred one of the following actions is recommended. Refer to the DMAC block guide for details about how this functionality is supported.

- The corresponding DMA channel should be disabled. This might be desirable for CFIFOs in single scan mode.
- The source address should be updated to pointed to a valid command which can be the first command in the queue that has just been transferred (cyclic queue), or the first command of any other CQueue. This is desirable for CFIFOs in continuous scan mode, and at some cases, for CFIFOs in single scan mode.

Figure 29-155. CQueue/CFIFO interface

### 29.7.2.2 RQueue/RFIFO transfers

In transfers involving RQueues and RFIFOs, the DMAC moves data from a single source to a queue destination as showed in Figure 29-156. The location of the data to be moved is indicated by the source address, and the final destination for that data, by the destination address. For every DMA request issued by the EQADC, the DMAC has to be configured to transfer a single result (16-bit data), pointed to by the source address, from the RFIFO pop register to the RQueue, pointed to by the destination address. After the service of a DMA request is completed, the destination address has to be updated to point to the location where the next 16-bit result will be stored. The source address remains unchanged. When the last expected result is written to the RQueue, one of the following actions is recommended. Refer to the DMAC block guide for details about how this functionality is supported.

- The corresponding DMA channel should be disabled.
- The destination address should be updated pointed to the next location where new coming results are stored, which can be the first entry of the current RQueue (cyclic queue), or the beginning of a new RQueue.

Figure 29-156. RQueue/RFIFO Interface

### 29.7.3 Sending immediate command setup example

In the EQADC, there is no immediate command register for sending a command immediately after writing to that register. However, a CFIFO can be configured to perform the same function as an immediate command register. The following steps illustrate how to configure CFIFO5 as an immediate command CFIFO. The results will be returned to RFIFO5.

1. Configure [EQADC Interrupt and DMA Control Register 0 \(EQADC\\_IDCR0\)](#).
  - Clear CFIFO Fill Enable5 (CFFE5 = 0) in EQADC\_IDCR2.
  - Clear CFIFO Underflow Interrupt Enable5 (CFUIE5 = 0) in EQADC\_IDCR2.
  - Clear RFDS5 to configure the EQADC to generate interrupt requests to pop result data from RFIFO5.
  - Set RFIFO Drain Enable5 (RFDE5 = 1) in EQADC\_IDCR2.
2. Configure [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#).
  - Write "1" to CFINV5 in EQADC\_FCR2. This will invalidate the contents of CFIFO5.
  - Set MODE5 to Continuous-Scan Software Trigger mode in EQADC\_CFCR2.
3. To transfer a command, write it to EQADC CFIFO Push Register 5 (EQADC\_CFPR5) with Message Tag = 0b0101. See [EQADC CFIFO Push Register \(EQADC\\_CFPRn\)](#).
4. Up to four commands can be queued in CFIFO5. Check the CFCTR5 status in EQADC\_FISR5 before pushing another command to avoid overflowing the CFIFO. See [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISRn\)](#).
5. When the EQADC receives a conversion result for RFIFO5, it generates an interrupt request. RFIFO Pop Register 5 (EQADC\_RFPR5) can be popped to read the result. See [EQADC Result FIFO Pop Register \(EQADC\\_RFPRn\)](#).

## 29.7.4 Modifying queues

More CQueues may be needed than the six supported by the EQADC. These additional CQueues can be supported by interrupting command transfers from a configured CFIFO, even if it is TRIGGERED and transferring, modifying the corresponding CQueue in the RAM or associating another CQueue to it, and restarting the CFIFO. More details on disabling a CFIFO are described in [Disabled Mode](#).

1. Determine the resumption conditions when later resuming the scan of the CQueue at the point before it was modified.
  - Change MODEx in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#) to Disabled. See [Disabled Mode](#) for a description of what happens when MODEx is changed to Disabled.

- Poll CFSx until it becomes IDLE in [EQADC CFIFO Status Register \(EQADC\\_CFSR\)](#).
  - Read and save TC\_CFx in [EQADC CFIFO Transfer Counter Register 0 \(EQADC\\_CFTCR0\)](#) for later resuming the scan of the queue. The TC\_CFx provides the point of resumption.
  - Since all result data may not have been stored in the appropriate RFIFO at the time MODEx is changed to disable, wait for all expected results to be stored in the RFIFO/RQueue before reconfiguring the DMAC to work with the modified RQueue. The number of results that must return can be estimated from the TC\_CFx value obtained above.
2. Disable the DMAC from responding to the DMA request generated by CFFFx and RFDFx in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISRn\)](#).
  3. Write "0x0000" to the TC\_CFx field.
  4. Load the new configuration and conversion commands into RAM. Configure the DMAC to support the new CQueue/RQueue, but do not configure it yet to respond to DMA requests from CFIFOx/RFIFOx.
  5. If necessary, modify [EQADC Interrupt and DMA Control Register 0 \(EQADC\\_IDCR0\)](#) to suit the modified CQueue.
  6. Write "1" to CFINVx in [EQADC CFIFO Control Register 0 \(EQADC\\_CFCR0\)](#) to invalidate the entries of CFIFOx. Perform any other modifications to EQADC\_CFCR except changing MODEx from Disabled.
  7. Configure the DMAC to respond to DMA requests generated by CFFFx and RFDFx.
  8. Change MODEx to the modified CFIFO operation mode. Write "1" to SSEx to trigger CFIFOx if MODEx is software trigger.

### 29.7.5 CQueue and RQueues usage

[Figure 29-157](#) is an example of CQueue and RQueue usage. It shows the CQueue0 commands requesting results that will be stored in RQueue0 and RQueue1, and CQueue1 commands requesting results that will be stored only in RQueue1. Some Command Messages request data to be returned from the on-chip ADC, but some only configure them and do not request returning data. When a CQueue contains both write and read commands like CQueue0, the CQueue and RQueue entries will not be aligned; as shown in [Figure 29-157](#), the result for the second command of CQueue0 is the first entry of RQueue0. The figure also shows that CQueue and RQueue entries can also become

unaligned even if all commands in a CQueue request data as CQueue1. CQueue1 entries became unaligned to RQueue1 entries because a result requested by the forth CQueue0 command was sent to RQueue1. This happens because the system can be configured so that several CQueues can have its results sent to a single RQueue.

Figure 29-157. EQADC Command and Result Queues

## 29.7.6 ADC Result Calibration

The ADC result calibration process consists of two steps: determining the gain and offset calibration constants, and calibrating the raw results generated by the on-chip ADCs by solving the following equation discussed in [ADC calibration feature](#).

$$\text{CAL\_RES} = \text{GCC} * \text{RAW\_RES} + \text{OCC} + 2$$

**Figure 29-158. Equation for CAL\_RES**

The calibration constants GCC and OCC can be calculated from equation [Figure 29-159](#), [Figure 29-160](#), and [Figure 29-161](#) provided that two pairs of expected (CAL\_RES) and measured (RAW\_RES) result values are available for two different input voltages. Most likely calibration points to be used are 25% VREF<sup>7</sup> and 75% VREF since they are far apart but not too close to the end points of the full input voltage range. This allows for calculations of more representative calibration constants. The EQADC provides these voltages via channel numbers 43 and 44. The raw, uncalibrated results for these input voltages are obtained by converting these channels with conversion commands that have the CAL bit negated.

The transfer equations for when sampling these reference voltages are:

$$\text{CAL\_RES}_{75\% \text{VREF}} = \text{GCC} * \text{RAW\_RES}_{75\% \text{VREF}} + \text{OCC} + 2;$$

$$\text{CAL\_RES}_{25\% \text{VREF}} = \text{GCC} * \text{RAW\_RES}_{25\% \text{VREF}} + \text{OCC} + 2;$$

Thus;

$$\text{GCC} = (\text{CAL\_RES}_{75\% \text{VREF}} - \text{CAL\_RES}_{25\% \text{VREF}}) / (\text{RAW\_RES}_{75\% \text{VREF}} - \text{RAW\_RES}_{25\% \text{VREF}})$$

**Figure 29-159. Equation for GCC**

$$\text{OCC} = \text{CAL\_RES}_{75\% \text{VREF}} - \text{GCC} * \text{RAW\_RES}_{75\% \text{VREF}} - 2$$

**Figure 29-160. Equation for OCC, form 1**

or

$$\text{OCC} = \text{CAL\_RES}_{25\% \text{VREF}} - \text{GCC} * \text{RAW\_RES}_{25\% \text{VREF}} - 2$$

**Figure 29-161. Equation for OCC, form 2**

After being calculated, the GCC and OCC values must be written to ADC registers: [ADC0/1 Gain Calibration Constant Registers \(ADC0\\_GCCR and ADC1\\_GCCR\)](#) and [ADC0/1 Offset Calibration Constant Registers \(ADC0\\_OCCR and ADC1\\_OCCR\)](#) using write configuration commands.

7. VREF=VRH-VRL

The EQADC will automatically calibrate the results, according to equation [Figure 29-158](#), of every conversion command that has its CAL bit asserted using the GCC and OCC values stored in the ADC calibration registers.

### 29.7.6.1 MAC configuration procedure

The following steps illustrate how to configure the calibration hardware, namely, determining the values of the gain and offset calibration constants, and the writing of these constants to the calibration registers. The procedure below should be performed for ADC0 and for ADC1.

1. Convert channel 44 with a command that has its CAL bit negated and obtain the raw, uncalibrated result for 25%VREF (RAW\_RES<sub>25%VREF</sub>).
2. Convert channel 43 with a command that has its CAL bit negated and obtain the raw, uncalibrated result for 75%VREF (RAW\_RES<sub>75%VREF</sub>).
3. Since the expected values for the conversion of these voltages are known (CAL\_RES<sub>25%VREF</sub> and CAL\_RES<sub>75%VREF</sub>), GCC and OCC values can be calculated from [Figure 29-159](#) and [Figure 29-160](#) using these values, and the ones determined in steps 1 and 2.
4. Reformat GCC and OCC to the proper data formats as specified in [MAC unit and operand data format](#). GCC is an unsigned 15-bit fixed point value and OCC is a signed 14-bit value.
5. Write GCC value to [ADC0/1 Gain Calibration Constant Registers \(ADC0\\_GCCR and ADC1\\_GCCR\)](#), and OCC value to [ADC0/1 Offset Calibration Constant Registers \(ADC0\\_OCCR and ADC1\\_OCCR\)](#) using write configuration commands.

### 29.7.6.2 Example

The raw results obtained when sampling reference voltages 25%VREF and 75%VREF were, respectively, 3798 and 11592. The results that should have been obtained from the conversion of these reference voltages are, respectively, 4096 and 12288. Therefore, using equations [Figure 29-159](#) and [Figure 29-160](#), the gain and offset calibration constants are:

$$GCC = (12288 - 4096) / (11592 - 3798) = 1.05106492 \rightarrow 1.05102539 = 0x4344$$

$$OCC = 12288 - 1.05106492 * 11592 - 2 = 102.06 \rightarrow 102 = 0x0066$$

Table 29-145 shows, for this particular case, examples of how the result values change according to GCC and OCC when result calibration is executed (CAL=1) and when it is not (CAL=0).

**Table 29-145. Calibration example**

| Input voltage | Raw result (CAL=0) |         | Calibrated result (CAL=1) |           |
|---------------|--------------------|---------|---------------------------|-----------|
|               | Hexadecimal        | Decimal | Hexadecimal               | Decimal   |
| 25% VREF      | 0x0ED6             | 3798    | 0x1000                    | 4095.794  |
| 75% VREF      | 0x2D48             | 11592   | 0x3000                    | 12287.486 |

### 29.7.6.3 Quantization error reduction during calibration

Figure 29-162 shows how the ADC transfer curve changes due to the addition of two to the MAC output during the calibration - see MAC output equation at [Overview](#) . The maximum absolute quantization error is reduced by half leading to an increase in accuracy.

Figure 29-162. Quantization error reduction during calibration

### 29.7.7 EQADC versus QADC

This section describes how the EQADC upgrades the QADC functionality. The section also provides a comparison between the EQADC and QADC in terms of their functionality. This section targets the users familiar with terminology in QADC. [Figure 29-163](#) is an overview of a QADC. [Figure 29-164](#) is an overview of the EQADC system.

Figure 29-163. QADC overview

Figure 29-164. EQADC system overview

The EQADC system consists of queues in RAM, an external device, the EQADC, and on-chip ADCs. As compared with the QADC, the EQADC system requires extra hardware.

- A DMA or an MCU is required to move data between the EQADC's FIFOs and Queues in the system memory.

Since there are only FIFOs inside the EQADC, much of the terminology or use of the register names, register contents, and signals of the EQADC involve "FIFO" instead of "Queue". These register names, register contents, and signals are functionally equivalent to the "Queue" counterparts in the QADC. [Table 29-146](#) lists how the EQADC register, register contents, and signals are related to QADC.

**Table 29-146. Terminology comparison between QADC and EQADC**

| QADC terminology                     | EQADC terminology                                                 | Function                                                                                                                                                                                                                                                                                                                                                                                                                |
|--------------------------------------|-------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| CCW                                  | Command Message                                                   | In the QADC, the hardware only executes conversion command words.<br><br>In the EQADC, not all commands are conversion commands; some are configuration commands.                                                                                                                                                                                                                                                       |
| Queue Trigger                        | CFIFO Trigger                                                     | In the QADC, a trigger event is required to start the execution of a queue.<br><br>In the EQADC, a trigger event is required to start command transfers from a CFIFO. When a CFIFO is TRIGGERED and transferring, commands are continuously moved from CQueues to CFIFOs. Thus, the trigger event initiates the "execution of a queue" indirectly.                                                                      |
| Current Word Pointer Queue x (CWPQx) | Counter Value of Commands Transferred from Command FIFOx (TC_CFx) | In the QADC, CWPQx allows the last executed command on queue x to be determined.<br><br>In the EQADC, the TC_CFx value allows the last transferred command on CQueue x to be determined.                                                                                                                                                                                                                                |
| Queue Pause Bit (P)                  | CFIFO Pause Bit                                                   | In the QADC, detecting a pause bit in the CCW will pause the queue execution.<br><br>In the EQADC, detecting a pause bit in the Command will pause command transfers from a CFIFO.                                                                                                                                                                                                                                      |
| Queue Operation Mode (MQx)           | CFIFO Operation Mode (MODEx)                                      | The EQADC supports all queue operation modes in the QADC except operation modes related to a periodic timer. A timer elsewhere in the system can provide the same functionality if it is connected to ETRIGx.                                                                                                                                                                                                           |
| Queue Status (QS)                    | CFIFO Status (CFSx)                                               | In the QADC, the Queue Status is read to check whether a queue is idle, active, paused, suspended, or trigger pending.<br><br>In the EQADC, the CFIFO Status is read to check whether a queue is IDLE, WAITING FOR TRIGGER (idle or paused in QADC), or TRIGGERED (suspended or trigger pending in QADC). What CFIFO is currently "active" can be determined by reading the LCFTCBn field on the EQADC_CFSSR registers. |

The EQADC and QADC also have similar procedures for the configuration or execution of applications. [Table 29-147](#) shows the steps required for the QADC versus the steps required for the EQADC system.

**Table 29-147. Usage comparison between QADC and EQADC system**

| Procedure                    | QADC                                                      | EQADC System                                        |

## Chapter 30

# Temperature Sensor (TSENS)

### 30.1 Chip-specific Temperature Sensor information

This chip has two instances of the Temperature Sensor.

#### 30.1.1 Temperature Sensor programming control

The control and status registers for the Temperature Sensor are implemented in the PMC digital interface.

#### 30.1.2 Accessing TSC parameters

The Temperature Sensor Calibration (TSC) parameters, including TSCA and TSCB, are used to calculate device temperature.

See the UTEST flash memory map for the specific locations of the TSC parameter values.

#### 30.1.3 Temperature name alignment

The Temperature Sensor modules and Power Management Controller (PMC) module use different terminology to refer to the same temperature points. The following table aligns the terminology.

**Table 30-1. Temperature Sensor and PMC temperature terminology**

| Temperature | Temperature Sensor name | PMC name      |
|-------------|-------------------------|---------------|
| -40°C       | Low temperature         | Temperature 0 |
| 150°C       | High temperature        | Temperature 2 |

## 30.2 Introduction

The device includes two on-chip temperature sensors. The temperature sensor module monitors device temperature and delivers one analog output signal and two digital output signals each (under- and over-temperature flags). The analog output consists of a voltage signal directly proportional to the internal junction temperature. The analog output is connected to an input channel of an ADC on the device (see the ADC details for the channel number). The internal junction temperature must be calculated by software based on the sampled temperature sensor voltage; sampled bandgap reference voltage, which comes from another module; and calibration parameter values stored in internal flash memory. The two digital outputs, connected to the PMC module, are used to signal under- and over-temperature operating conditions.

The digital outputs signal when the junction temperature drifts below the low temperature threshold or above the high temperature threshold. These signals notify the device to take action to appropriately adjust the device temperature in response to an out-of-specification low or high temperature operating condition. Calibration parameter values associated with the temperature threshold detection feature are determined and stored in internal flash memory during production testing at the factory.

## 30.3 Functional Description

The temperature sensor generates one analog output voltage,  $V_{TSENS}(T)$ , which is proportional to the absolute current junction temperature of the device, and two digital outputs that signal whether the junction temperature has reached either a pre-set low temperature threshold or a pre-set high temperature threshold.

An on-chip ADC module is used to convert the analog output voltage, as well as the bandgap reference voltage, into a digital representation. These values, along with parameter values stored in on-chip flash memory, are used by software to calculate the device junction temperature.

### 30.3.1 Temperature threshold detection (digital output generation)

Temperature threshold trimming values are adjusted through calibration during factory test and stored in on-chip flash memory. While enabled, if a new trimming value is loaded into the Temperature Sensor module, it may take up to 1 microsecond for the digital outputs to be updated to reflect the new trimming condition.

When the temperature threshold detection feature is enabled, the temperature sensor monitors the internal junction temperature of the chip and asserts a signal if any of the following temperature thresholds are crossed.

- The low temperature digital output signals if the junction temperature falls below the low temperature threshold ( $-40^{\circ}\text{C}$ ).
- The high temperature digital output signals if the junction temperature rises above the high temperature threshold ( $150^{\circ}\text{C}$ ).

The threshold detection circuit is calibrated with respect to the factory-test temperatures: the low temperature threshold is trimmed to match the cold insertion test temperature (nominally equal to  $-40^{\circ}\text{C}$ ), and the high temperature threshold is trimmed to match the hot insertion test temperature (nominally equal to  $150^{\circ}\text{C}$ ). In other words, the thresholds are not trimmed to absolute values of temperature but to the specific temperatures for which the device is validated during factory test.

Hysteresis is applied whenever outputs transition to a logic level low in order to eliminate spurious toggling. Digital output behavior is illustrated on [Figure 30-1](#).

**Figure 30-1. Digital output behavior with temperature**

### 30.3.2 Linear temperature sensor (analog output generation)

When analog output generation is enabled, the temperature sensor outputs a voltage proportional to the internal junction temperature of the chip. This analog voltage signal is converted into a digital code by an on-chip ADC. The temperature value is obtained from a linear voltage-temperature relation with coefficients adjusted by calibration parameters extracted during factory test and programmed into flash memory.

## 30.4 Temperature formula

The system chain that translates device junction temperature into a digital variable is composed of the temperature sensor, a bandgap reference voltage source and the on-chip ADC. Both analog output voltages of the temperature sensor and the bandgap reference voltage source must be converted by the ADC into digital codes to obtain the device junction temperature. The temperature formula shown in [Figure 30-2](#) is used to calculate internal device junction temperature.

$$T = (232 + TSCA \times 2^{-6}) \times \frac{V_{TSENS\_CODE}(T)}{V_{BG\_CODE}(T)} - (273 + TSCB \times 2^{-4}) [^{\circ}\text{C}]$$

Where:

$$TSCA = \left( \frac{T_{HIGH} - T_{LOW}}{V_{TSENS\_CODE}(T_{HIGH}) - V_{TSENS\_CODE}(T_{LOW})} \times V_{BG\_CODE}(T_{FINAL}) - 232 \right) \times 2^6$$

$$TSCB = \left( \frac{T_{HIGH} - T_{LOW}}{V_{TSENS\_CODE}(T_{HIGH}) - V_{TSENS\_CODE}(T_{LOW})} \times V_{TSENS\_CODE}(T_{LOW}) - T_{LOW} - 273 \right) \times 2^4$$

$$V_{TSENS\_CODE}(T_{LOW}) = \frac{V_{TSENS}(T_{LOW})}{V_{ref0}} \times 2^{12}$$

$$V_{TSENS\_CODE}(T_{HIGH}) = \frac{V_{TSENS}(T_{HIGH})}{V_{ref0}} \times 2^{12}$$

$$V_{BG\_CODE}(T_{FINAL}) = \frac{V_{BG}(T_{FINAL})}{V_{ref0}} \times 2^{12}$$

$$V_{BG\_CODE}(T) = \frac{V_{BG}(T)}{V_{ref}} \times 2^{12}$$

$$V_{TSENS\_CODE}(T) = \frac{V_{TSENS}(T)}{V_{ref}} \times 2^{12}$$

**Notes:**

- TSCA and TSCB are 16-bit signed integer constants stored in flash memory during factory test and calibration
- $V_{TSENS}(T)$  is the temperature sensor output sampled by the ADC
- $V_{BG}(T)$  is the bandgap reference voltage sampled by the ADC at temperature T
- $V_{ref}$  is the ADC reference voltage in normal usage of the device
- $V_{ref0}$  is the ADC reference voltage during factory calibration
- $T_{LOW}$  is the low temperature factory calibration temperature
- $T_{HIGH}$  is the hot temperature factory calibration temperature
- $T_{FINAL}$  is the final insertion factory calibration temperature

**Figure 30-2. Temperature formula**

Parameters TSCA and TSCB are 16-bit signed integer constants stored during factory test and calibration that need to be used in the temperature formula to calculate device junction temperature. The values for TSCA and TSCB translate into positive or negative shifts of the linear relation coefficients that compensate for manufacturing process variation. [Figure 30-2](#) shows how parameters TSCA and TSCB are calculated in terms of the actual variables measured during factory calibration.

## 30.5 Calculating device temperature

Software must perform the following steps in order to calculate device temperature.

#### Calculating device temperature

1. Read the bandgap reference voltage  $V_{\text{TSENS\_CODE}}(T)$  using the on-chip ADC module.
2. Read the temperature sensor output  $V_{\text{BG\_CODE}}(T)$  using the on-chip ADC module.
3. Retrieve parameters TSCA and TSCB from flash memory.
4. Calculate T according to the formula shown in [Figure 30-2](#).

#### Note

Temperature Formula may be calculated using signed 32-bit (integer) operations showing negligible precision loss.

# Chapter 31

## System Timer Module (STM)

### 31.1 Chip-specific STM information

This chip has one instance of the STM.

### 31.2 Introduction

This section provides an overview, list of features, and modes of operation for the STM.

#### 31.2.1 Overview

The System Timer Module (STM) is a 32-bit timer designed to support commonly required system and application software timing functions. The STM includes a 32-bit up counter and four 32-bit compare channels with a separate interrupt source for each channel. The counter is driven by the system clock divided by an 8-bit prescale value (1 to 256).

#### 31.2.2 Features

The STM has the following features:

- One 32-bit up counter with 8-bit prescaler
- Four 32-bit compare channels
- Independent interrupt source for each channel
- Counter can be stopped in debug mode

### 31.2.3 Modes of operation

The STM supports two device modes of operation: normal and debug. When the STM is enabled in normal mode, its counter runs continuously. In debug mode, operation of the counter is controlled by the FRZ bit in the STM\_CR register. If the FRZ bit is set, the counter is stopped in debug mode, otherwise it continues to run.

## 31.3 External signal description

The STM does not have any external interface signals.

## 31.4 Memory map and registers

The STM programming model includes a group of 32-bit registers—a module control register, a counter value register, and three registers for each channel.

The STM registers can only be accessed using 32-bit (word) accesses. Attempted references using a different size or to a reserved address generates a bus error termination.

**STM memory map**

| Address offset (hex) | Register name                             | Width (in bits) | Access | Reset value | Section/page                |

STM\_CMPn field descriptions (continued)

| Field | Description |
|-------|-------------|
|-------|-------------|

31.5 Functional description

The STM has one 32-bit up counter (STM\_CNT) that is used as the time base for all channels. When enabled, the counter increments at the system clock frequency divided by a prescale value. The STM\_CR[CPS] field sets the divider to any value in the range from 1 to 256. The counter is enabled with the STM\_CR[TEN] bit. When enabled in normal mode, the counter continuously increments. When enabled in debug mode, the counter operation is controlled by the STM\_CR[FRZ] bit. When the STM\_CR[FRZ] bit is set, the counter is stopped in debug mode; otherwise, it continues to run in debug mode. The counter rolls over at 0xFFFF\_FFFF to 0x0000\_0000 with no restrictions at this boundary.

The STM has four identical compare channels. Each channel includes a channel control register (STM\_CCRn), a channel interrupt register (STM\_CIRn), and a channel compare register (STM\_CMPn). The channel is enabled by setting the STM\_CCRn[CEN] bit. When enabled, the channel will set the STM\_CIRn[CIF] bit and generate an interrupt request when the channel compare register matches the timer counter. The interrupt request is cleared by writing 1 to the STM\_CIRn[CIF] bit. A write of 0 to the STM\_CIRn[CIF] bit has no effect.

NOTE

The STM counter does not advance when the system clock is stopped.

# Chapter 32

## Software Watchdog Timer (SWT)

### 32.1 Chip-specific SWT information

This chip has two instances of the SWT module: SWT\_A and SWT\_B.

#### 32.1.1 SWT register reset values

The following table identifies chip-specific reset values of SWT registers.

**Table 32-1. Chip-specific SWT register reset values**

| Register | SWT_A                   | SWT_B      |
|----------|-------------------------|------------|
| CR       | FF00_010Bh <sup>1</sup> | FF00_010Ah |
| TO       | 0005_FCD0h              | 0005_FCD0h |

1. This value is present after a hardware reset and before the BAM executes. The BAM code (RCHW) might change it before application code executes. See [Reset Configuration Half Word \(RCHW\)](#) for more information.

#### 32.1.2 SWT time-out events and invalid accesses: configuring reset and interrupt requests

To configure the results of SWT time-out events and invalid accesses for an SWT that is enabled (SWT\_CR[WEN] is 1):

- Program these [SWT Control Register \(SWT\\_CR\)](#) fields:

- **ITR** determines when the outcome of a time-out event is a reset request or an interrupt request.
- **RIA** determines when the outcome of an invalid access is a reset request or a bus error.
- Program FCCU reactions to the non-critical faults (NCFs) that are associated with these reset and interrupt requests.

See **FCCU fault inputs** for the default reaction to each NCF.

### CAUTION

For any NCF that receives an SWT reset request: If the default FCCU reaction is no reset but the intended application requires a reset, configure the FCCU's reaction to be a reset.

The following table shows the NCFs to which the SWT generates reset and interrupt requests for time-out events.

**Table 32-2. Routing of SWT reset and interrupt requests for time-out events**

| SWT instance | SWT_CR[ITR] is 0                        | SWT_CR[ITR] is 1                                |                                                        |
|--------------|-----------------------------------------|-------------------------------------------------|--------------------------------------------------------|
|              | Any time-out generates reset request to | Initial time-out generates interrupt request to | Second consecutive time-out generates reset request to |
| SWT_A        | NCF[14]                                 | IRQ[8] and NCF[16]                              | NCF[14]                                                |
| SWT_B        | NCF[15]                                 | IRQ[501]                                        | NCF[15]                                                |

The following table shows the NCFs to which the SWT can generate reset requests for invalid accesses.

**Table 32-3. Routing of SWT reset requests for invalid accesses**

| SWT instance | SWT_CR[RIA] is 0                   | SWT_CR[RIA] is 1                                  |
|--------------|------------------------------------|---------------------------------------------------|
| SWT_A        | Invalid access generates bus error | Invalid access generates reset request to NCF[14] |
| SWT_B        | Invalid access generates bus error | Invalid access generates reset request to NCF[15] |

## 32.2 Introduction

This section provides an overview, list of features, and modes of operation for the SWT.

### 32.2.1 Overview

The Software Watchdog Timer (SWT) is a peripheral module that can prevent system lockup in situations such as software getting trapped in a loop or if a bus transaction fails to terminate. When enabled, the SWT requires periodic execution of a watchdog servicing operation. The servicing operation resets the timer to a specified time-out period. If this servicing action does not occur before the timer expires, the SWT generates an interrupt or hardware reset request. The SWT can be configured to generate a reset request or interrupt on an initial time-out. The SWT always generates a reset request on a second consecutive time-out.

### 32.2.2 Features

The SWT has the following features:

- 32-bit time-out register to set the time-out period
- Programmable selection of system or oscillator clock, for timer operation
- Programmable selection of window mode or regular servicing
- Programmable selection of reset request or interrupt on an initial time-out
- Programmable selection of the servicing mode
- Master access protection
- Hard and soft configuration lock bits
- Reset configuration inputs allow timer to be enabled out of reset

### 32.2.3 Modes of operation

The SWT supports these device modes of operation:

- Normal
- Debug
- Stop

When the SWT is enabled in normal mode, its counter runs continuously. In debug mode, operation of the counter is controlled by the FRZ bit in the SWT\_CR. If the FRZ bit is set, the counter is stopped in debug mode; otherwise it continues to run. In stop mode, operation of the counter is controlled by the STP bit in the SWT\_CR. If the STP bit is set, the counter is stopped in stop mode; otherwise it continues to run.

### 32.3 External signal description

The SWT module does not have any external interface signals.

### 32.4 Memory Map and Registers

The SWT programming model has seven 32-bit registers. The programming model can be accessed using only 32-bit (word) accesses.

Any of the following attempted accesses are invalid:

- References using non-32-bit access sizes
- Writes to read-only registers
- Writes of incorrect values to SWT\_SR when the SWT is enabled
- Accesses to reserved addresses
- Accesses by masters without permission

For an enabled SWT, an invalid access generates a reset request if SWT\_CR[RIA] is 1. An invalid access generates a bus error if SWT\_CR[RIA] is 0.

If either HLK or SLK in SWT\_CR is 1, then the SWT\_CR, SWT\_TO, SWT\_WN, and SWT\_SK registers are read-only.

**SWT memory map**

| Address offset (hex) | Register name                        | Width (in bits) | Access | Reset value                 | Section/ page               |
|----------------------|--------------------------------------|-----------------|--------|-----------------------------|-----------------------------|
| 0                    | SWT Control Register (SWT_CR)        | 32              | R/W    | <a href="#">See section</a> | <a href="#">32.4.1/1163</a> |
| 4                    | SWT Interrupt Register (SWT_IR)      | 32              | R/W    | 0000_0000h                  | <a href="#">32.4.2/1166</a> |
| 8                    | SWT Time-out Register (SWT_TO)       | 32              | R/W    | <a href="#">See section</a> | <a href="#">32.4.3/1167</a> |
| C                    | SWT Window Register (SWT_WN)         | 32              | R/W    | 0000_0000h                  | <a href="#">32.4.4/1167</a> |
| 10                   | SWT Service Register (SWT_SR)        | 32              | W      | 0000_0000h                  | <a href="#">32.4.5/1168</a> |
| 14                   | SWT Counter Output Register (SWT_CO) | 32              | R      | 0000_0000h                  | <a href="#">32.4.6/1168</a> |
| 18                   | SWT Service Key Register (SWT_SK)    | 32              | R/W    | 0000_0000h                  | <a href="#">32.4.7/1169</a> |

### 32.4.1 SWT Control Register (SWT\_CR)

#### NOTE

The reset value of this register is implementation specific. See the chip-specific SWT information.

The SWT\_CR contains fields for configuring and controlling the SWT.

This register is read-only if either SWT\_CR[HLK] or SWT\_CR[SLK] is 1.

Address: 0h base + 0h offset = 0h

**32.5 Functional description****32.5.1 Introduction**

The SWT is a 32-bit window watchdog timer designed to enable the system to recover in situations such as software getting trapped in a loop or if a bus transaction fails to terminate. It includes:

- a control register (SWT\_CR),
- an interrupt register (SWT\_IR),
- a time-out register (SWT\_TO),
- a window register (SWT\_WN),
- a service register (SWT\_SR),

- a counter output register (SWT\_CO), and
- a service key register (SWT\_SK).

Accesses to SWT registers occur with no peripheral bus wait states. (The peripheral bus bridge may add one or more system wait states.) However, due to synchronization logic in the SWT design, recognition of the service sequence or configuration changes may require up to three system plus seven counter clock cycles.

### **32.5.1.1 SWT\_CR register**

The SWT\_CR register includes bits to enable the timer, set configuration options, and lock configuration of the module. The watchdog is enabled by setting the SWT\_CR[WEN] bit. The reset value of the SWT\_CR[WEN] bit is device specific.<sup>3</sup> If the reset value of this bit is 1, the watchdog starts operation automatically after reset is released. Some devices can be configured to clear this bit automatically during the boot process.

### **32.5.1.2 SWT\_TO register**

The SWT\_TO register holds the watchdog time-out period in clock cycles unless the value is less than 0x100, in which case the time-out period is set to 0x100. When the SWT is enabled, the time-out period is loaded into an internal 32-bit down counter each time a valid service operation is performed. The SWT\_CR[CSL] bit selects which clock (system or oscillator) is used to drive the down counter.

### **32.5.1.3 SWT\_CO register**

The SWT\_CO register shows the value of the down counter when the watchdog is disabled. When the watchdog is enabled this register is cleared. The value shown in this register can lag behind the value in the internal counter for up to six system plus eight counter clock cycles.

The SWT\_CO register can be used during a software self test of the SWT. For example, the SWT can be enabled and not serviced for a fixed period of time less than the time-out value. Then the SWT can be disabled (SWT\_CR[WEN] cleared) and the value of the SWT\_CO register read to determine if the internal down counter is working properly.

---

3. See the chip-specific SWT information.

## 32.5.2 Configuration locking

The configuration of the SWT can be locked through use of either a soft lock or a hard lock. In either case, when locked, the SWT\_CR, SWT\_TO, SWT\_WN and SWT\_SK registers are read-only.

### 32.5.2.1 Hard lock

The hard lock is enabled by setting the SWT\_CR[HLK] bit, which can only be cleared by a reset.

### 32.5.2.2 Soft lock

The soft lock is enabled by setting the SWT\_CR[SLK] bit and is cleared by writing the unlock sequence to the service register.

## 32.5.3 Unlock sequence

The unlock sequence is a write of 0xC520 followed by a write of 0xD928 to the SWT\_SR[WSC] field. There is no timing requirement between the two writes. The unlock sequence logic ignores service sequence writes and recognizes the 0xC520, 0xD928 sequence regardless of previous writes. The unlock sequence can be written at any time and does not require the SWT\_CR[WEN] bit to be set.

## 32.5.4 Servicing operations

When enabled, the SWT requires periodic execution of a servicing operation that is determined by the SWT\_CR[SMD] field. Properly servicing the watchdog loads the internal down counter with the time-out period. The servicing modes are:

- fixed service sequence
- keyed service sequence

### 32.5.4.1 Fixed service sequence mode

If the SWT\_CR[SMD] field is 00b, the fixed service sequence mode is selected, which requires writing 0xA602, then 0xB480 to the SWT\_SR[WSC] field to service the watchdog. There is no timing requirement between the two writes and the service sequence logic ignores unlock sequence writes.

### 32.5.4.2 Keyed service sequence mode

If the SWT\_CR[SMD] field is 01b, then the keyed service sequence mode is selected, which requires writing two pseudorandom keys to the SWT\_SR[WSC] field to service the watchdog. The key values are determined by the pseudorandom key generator defined by the equation in the following figure. This algorithm will generate a sequence of  $2^{16}$  different key values before repeating. The state of the key generator is held in the SWT\_SK register. For example, if SWT\_SK[SK] is 0x0100, then the service sequence keys are 0x1103, 0x2136. In this mode, each time a valid key is written to the SWT\_SR register, the SWT\_SK register is updated. So, after servicing the watchdog by writing 0x1103 and then 0x2136 to the SWT\_SR[WSC] field, SWT\_SK[SK] is 0x2136 and the next key sequence is 0x3499, 0x7E2C.

$$SK_{n+1} = (17 \times SK_n + 3) \bmod 2^{16}$$

**Figure 32-8. Pseudorandom Key Generator**

### 32.5.4.3 Window mode

If window mode is enabled (SWT\_CR[WND] bit is 1), the service sequence must be applied in the last part of the time-out period defined by SWT\_WN.

- The window is open when the down counter is less than the value in SWT\_WN.
- Outside this window, service sequence writes are invalid accesses and generate a bus error or reset request depending on the value of SWT\_CR[RIA].

For example, if SWT\_TO is set to 5000 and SWT\_WN is set to 1000, the service sequence must be applied in the last 20% of the time-out period.

Synchronization logic in the watchdog design slightly delays when the window opens. This delay could be up to 3 system clock cycles plus 4 counter clock cycles.

### 32.5.5 Time-out

The SWT\_CR[ITR] bit controls the SWT's action taken when a time-out occurs.

- If the SWT\_CR[ITR] bit is 0, the SWT generates a reset request immediately on any time-out.
- If the SWT\_CR[ITR] bit is 1, an initial time-out causes the SWT to generate an interrupt and load the down counter with the time-out period.
  - The interrupt is indicated by the Time-out Interrupt Flag (SWT\_IR[TIF]).
  - Clear the interrupt by writing 1 to SWT\_IR[TIF].

If the service sequence is not written before the second consecutive time-out, the SWT generates a reset request.

### 32.5.6 Initialization

All registers should be initialized before setting the SWT\_CR[WEN] bit to enable the watchdog. Registers can be initialized in any sequence.

## Chapter 33

# Periodic Interrupt Timer (PIT-RTI)

### 33.1 Chip-specific PIT information

This chip has one instance of the PIT.

PIT channels can be used to trigger periodic ADC conversions via EQADC Command FIFOs. For more information, see:

- [eQADC Command FIFO Trigger Source Registers \(SIU\\_ISEL4\) to eQADC Command FIFO Trigger Source Registers \(SIU\\_ISEL7\) and eQADC Advance Trigger Source Register \(SIU\\_ISEL9\)](#)
- [SIU Trigger Burst Generators \(TBG\)](#)

### 33.2 Introduction

The PIT module is an array of timers that can be used to raise interrupts and triggers. It includes a dedicated Real Time Interrupt Timer (RTI), which runs on a separate clock and can be used for system wakeup

#### 33.2.1 Block diagram

The following figure shows the block diagram of the PIT-RTI module.

**Figure 33-1. Block diagram of the PIT-RTI**

### NOTE

See the chip-specific PIT information for the number of PIT channels used in this MCU.

## 33.2.2 Features

The main features of this block are:

- One RTI (Real-Time Interrupt) timer to wakeup the CPU
- Ability of timers to generate trigger pulses
- Ability of timers to generate interrupts
- Maskable interrupts
- Option to raise RTI interrupt, even when the bus clock is switched off

- Power saving with a separate input clock for the RTI timer. All other timers share one common core clock.
- Independent timeout periods for each timer

### 33.3 Signal description

The PIT module has no external pins.

### 33.4 Memory map/register description

This section provides a detailed description of all registers accessible in the PIT\_RTIC module.

- See the chip-specific PIT information for the number of PIT channels used in this MCU.
- The RTI registers should be programmed only when the RTI clock is running.

#### NOTE

Write request to a register must have the byte enable asserted for the bytes user wants to update.

**PIT\_LTMR64H field descriptions**

| Field       | Description                                                                                                                                     |
|-------------|-------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–31<br>LTH | Life Timer value<br><br>Shows the timer value of timer 1. If this register is read at a time t1, LTMR64L shows the value of timer 0 at time t1. |

33.4.3 PIT Lower Lifetime Timer Register (PIT\_LTMR64L)

This register is intended for applications that chain timer 0 and timer 1 to build a 64-bit lifetimer.

To use LTMR64H and LTMR64L, timer 0 and timer 1 need to be chained. To obtain the correct value, first read LTMR64H and then LTMR64L. LTMR64H will have the value of CVAL1 at the time of the first access, LTMR64L will have the value of CVAL0 at the time of the first access, therefore the application does not need to worry about carry-over effects of the running counter.

Access: User read only

Address: 0h base + E4h offset = E4h

PIT\_LTMR64L field descriptions

| Field       | Description                                                                                                                   |
|-------------|-------------------------------------------------------------------------------------------------------------------------------|
| 0–31<br>LTL | Life Timer value<br><br>Shows the value of timer 0 at the time LTMR64H was last read. It will only update if LTMR64H is read. |

33.4.4 Timer Load Value Register (PIT\_RTI\_LDVAL)

These registers select the timeout period for the timer interrupts.

In the case of the RTI, it will take several cycles until this value is synchronized into the RTI clock domain. For all other timers the value change is visible immediately. The synchronisation mechanism allows 0 wait states in this case.

Access: User read/write

Address: 0h base + F0h offset = F0h

**PIT\_RTI\_LDVAL field descriptions**

| Field       | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|-------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–31<br>TSV | <p>Timer Start Value</p> <p>Sets the timer start value. The timer will count down until it reaches 0, then it will generate an interrupt and load this register value again. Writing a new value to this register will not restart the timer; instead the value will be loaded after the timer expires. To abort the current cycle and start a timer period with the new value, the timer must be disabled and enabled again.</p> <p><b>NOTE:</b> The RTI timer must not be set to a value lower than 32 cycles, otherwise interrupts may be lost, as it takes several cycles to clear the RTI interrupt. For the other timers, this limit does not apply, however there will be practical limits, since the processor will require several cycles to service an interrupt.</p> |

**33.4.5 Current Timer Value Register (PIT\_RTI\_CVAL)**

These registers indicate the current timer position.

For the RTI timers, they show a value which is several cycles old, since it originates from a potentially different clock domain.

Access: User read only

Address: 0h base + F4h offset = F4h

**33.5 Functional description**

This section provides the functional description of the module.

### 33.5.1 General operation

This section gives detailed information on the internal operation of the module. Each timer can be used to generate trigger pulses and interrupts. Each interrupt is available on a separate interrupt line. Additionally the RTI timer can be used to wake up the processor.

#### 33.5.1.1 Timers / RTI

The timers generate triggers at periodic intervals, when enabled. The timers load the start values as specified in their LDVAL registers, count down to 0 and then load the respective start value again. Each time a timer reaches 0, it will generate a trigger pulse and set the interrupt flag.

All interrupts can be enabled or masked by setting TCTRLn[TIE]. A new interrupt can be generated only after the previous one is cleared. Since in the case of the RTI, clearing the interrupt crosses clock domains, a minimum load value of 32 must be maintained.

If desired, the current counter value of the timer can be read via the CVAL registers. The value of the RTI counter can be delayed considerably, as it is synchronized to the bus clock from the RTI clock domain.

The counter period can be restarted, by first disabling, and then enabling the timer with TCTRLn[TEN]. See the following figure.

**Figure 33-29. Stopping and starting a timer**

The counter period of a running timer can be modified, by first disabling the timer, setting a new load value, and then enabling the timer again. See the following figure.

**Figure 33-30. Modifying running timer period**

It is also possible to change the counter period without restarting the timer by writing LDVAL with the new load value. This value will then be loaded after the next trigger event. See the following figure.

**Figure 33-31. Dynamically setting a new load value**

### NOTE

- If the pause is initiated, when the timer is nearing 0 (CVALn = 0x0), the pause command may not make it to the IP before the timer expires and generates a trigger.
- Pause will be ignored if (CVALn = 0x0), but the trigger will remain asserted until the pause is removed. The user is recommended to remove Pause and then clear the interrupt TFLGn[TIF].
- If the timers are to be paused, sufficient time must be ensured for the IP to react.

### 33.5.1.2 Debug mode

In Debug mode, the timers will be frozen based on MCR[FRZ]. This is intended to aid software development, allowing the developer to halt the processor, investigate the current state of the system, for example, the timer values, and then continue the operation.

## 33.5.2 Interrupts

All the timers support interrupt generation. The RTI is typically used for system wakeup, but can be used for interrupt generation as well. See the MCU specification for related vector addresses and priorities.

Timer interrupts can be enabled by setting TCTRLn[TIE]. TFLGn[TIF] are set to 1 when a timeout occurs on the associated timer, and are cleared to 0 by writing a 1 to the corresponding TFLGn[TIF].

The PIT\_RTI generates a real time interrupt when the selected interrupt time period elapses. The RTI interrupt is disabled locally by setting TCTCRLn[TIE] to zero. The real time interrupt flag (TIF) is set to 1 when a timeout occurs, and is cleared by writing a 1 to the corresponding TFLGn[TIF]. The flag will be set regardless whether the interrupt is enabled.

The RTI can be used for periodic wakeup from a low-power mode. It can also be used to generate a general-purpose interrupt.

### 33.5.3 Chained timers

When a timer has chain mode enabled, it will only count after the previous timer has expired. So if timer n-1 has counted down to 0, counter n will decrement the value by one. This allows to chain some of the timers together to form a longer timer. The first timer (timer 0) cannot be chained to any other timer.

## 33.6 Initialization and application information

In the example configuration:

- The PIT clock has a frequency of 50 MHz.
- The RTI clock has a frequency of 10 MHz.
- The RTI creates a wakeup interrupt every 500 ms.
- Timer 1 creates an interrupt every 5.12 ms.
- Timer 3 creates a trigger event every 30 ms.

The PIT module must be activated by writing a 0 to MCR[MDIS].

The 50 MHz clock frequency equates to a clock period of 20 ns and the 10 MHz frequency equates to a clock period of 100 ns. Therefore, the RTI timer needs to trigger every  $500 \text{ ms} / 100 \text{ ns} = 5,000,000$  cycles. Timer 1 needs to trigger every  $5.12 \text{ ms} / 20 \text{ ns} = 256,000$  cycles and Timer 3 every  $30 \text{ ms} / 20 \text{ ns} = 1,500,000$  cycles. The value for the LDVAL register trigger is calculated as:

$\text{LDVAL trigger} = (\text{period} / \text{clock period}) - 1$

This means RTI LDVAL will be written with 004C4B3F hex; LDVAL1 and LDVAL3 must be written with 0x0003E7FF and 0x0016E35F respectively.

To generate the wakeup interrupt, the interrupt line must be enabled by writing 1 to the RTI TIE bit in the TCTRL register. To start the RTI, the TEN in the RTI TCTRL register must also be set.

The interrupt for Timer 1 is enabled by setting TCTRL1[TIE]. The timer is started by writing 1 to TCTRL1[TEN].

Timer 3 shall be used only for triggering. Therefore, Timer 3 is started by writing a 1 to TCTRL3[TEN]. TCTRL3[TIE] stays at 0.

The following example code matches the described setup:

```
// turn on PIT
PIT_MCR = 0x00;

// RTI
PIT_RTI_LDVAL = 0x004C4B3F; // setup RTI for 5000000 cycles
PIT_RTI_TCTRL = PIT_TIE; // let RTI generate interrupts
PIT_RTI_TCTRL |= PIT_TEN; // start RTI

// Timer 1
PIT_LDVAL1 = 0x0003E7FF; // setup timer 1 for 256000 cycles
PIT_TCTRL1 = TIE; // enable Timer 1 interrupts
PIT_TCTRL1 |= TEN; // start Timer 1

// Timer 3
PIT_LDVAL3 = 0x0016E35F; // setup timer 3 for 1500000 cycles
PIT_TCTRL3 |= TEN; // start Timer 3
```

## 33.7 Example configuration for chained timers

In the example configuration:

- The PIT clock has a frequency of 100 MHz.
- Timers 1 and 2 are available.
- An interrupt shall be raised every 1 minute.

The PIT module needs to be activated by writing a 0 to MCR[MDIS].

The 100 MHz clock frequency equates to a clock period of 10 ns, so the PIT needs to count for 6000 million cycles, which is more than a single timer can do. So, Timer 1 is set up to trigger every 6 s (600 million cycles). Timer 2 is chained to Timer 1 and programmed to trigger 10 times.

The value for the LDVAL register trigger is calculated as number of cycles-1, so LDVAL1 receives the value 0x23C345FF and LDVAL2 receives the value 0x00000009.

The interrupt for Timer 2 is enabled by setting TCTRL2[TIE], the Chain mode is activated by setting TCTRL2[CHN], and the timer is started by writing a 1 to TCTRL2[TEN]. TCTRL1[TEN] needs to be set, and TCTRL1[CHN] and TCTRL1[TIE] are cleared.

The following example code matches the described setup:

```
// turn on PIT
PIT_MCR = 0x00;

// Timer 2
PIT_LDVAL2 = 0x00000009; // setup Timer 2 for 10 counts
PIT_TCTRL2 = TIE; // enable Timer 2 interrupt
PIT_TCTRL2 |= CHN; // chain Timer 2 to Timer 1
PIT_TCTRL2 |= TEN; // start Timer 2

// Timer 1
PIT_LDVAL1 = 0x23C345FF; // setup Timer 1 for 600 000 000 cycles
PIT_TCTRL1 = TEN; // start Timer 1
```

## 33.8 Example configuration for the lifetime timer

To configure the lifetime timer, channels 0 and 1 need to be chained together.

First the PIT module needs to be activated by writing a 0 to the MDIS bit in the CTRL register, then the LDVAL registers need to be set to the maximum value.

The timer is a downcounter.

The following example code matches the described setup:

```
// turn on PIT
PIT_MCR = 0x00;

// Timer 1
PIT_LDVAL1 = 0xFFFFFFFF; // setup timer 1 for maximum counting period
PIT_TCTRL1 = 0x0; // disable timer 1 interrupts
PIT_TCTRL1 |= CHN; // chain timer 1 to timer 0
PIT_TCTRL1 |= TEN; // start timer 1

// Timer 0
PIT_LDVAL0 = 0xFFFFFFFF; // setup timer 0 for maximum counting period
PIT_TCTRL0 = TEN; // start timer 0
```

To access the lifetime, read first LTMR64H and then LTMR64L.

```
current_uptime = PIT_LTMR64H<<32;
current_uptime = current_uptime + PIT_LTMR64L;
```

# Chapter 34

## Enhanced Modular IO Subsystem (eMIOS)

### 34.1 Chip-specific eMIOS information

This has two eMIOS module instances: eMIOS\_0 and eMIOS\_1. The two modules are identical and located on different Peripheral Bridges.

#### 34.1.1 eMIOS channels and counter buses

Each eMIOS module instance has 16 channels, for a total of 32 channels. The 32 channels are split across the two instances to support redundancy for safety applications.

The following table shows the mapping of the 32 eMIOS external balls to the instance channels.

**Table 34-1. eMIOS channel mapping**

| eMIOS balls | Instance channels |         |
|-------------|-------------------|---------|
|             | eMIOS_0           | eMIOS_1 |
| 0-7         | 0-7               | —       |
| 8-15        | —                 | 0-7     |
| 16-23       | 16-23             | —       |
| 24-31       | —                 | 16-23   |

For both module instances, each set of implemented channels drives a counter bus:

- Channels 0-7 drive counter bus B.
- Channels 16-23 drive counter bus D.

## 34.1.2 eMIOS unimplemented channels

For both module instances, channels 8-15 and 24-31 are not implemented. References to features and functionality related to these channels—including registers, register fields, and counter buses—do not apply to this chip.

## 34.1.3 eMIOS interaction with other modules

The eMIOS modules interface with eTPU, DSPI, and IGF modules.

### 34.1.3.1 eMIOS global time base synchronization with eTPU

The Global Time Base Enable (GTBE) signal output of the eMIOS module instances, which is controlled by the eMIOS's MCR[GTBE] field, is ORed together with the GTBE signal output from the two eTPU instances. The ORed signal is then fed back to the GTBE input of all eMIOS and eTPU instances.

These connections enable global time base synchronization through the following procedure:

1. Negate the GTBE field in all eMIOS and eTPU instances.
2. Configure eMIOS and eTPU channels.
3. Assert the GTBE field in one of the eMIOS or eTPU instances.

### 34.1.3.2 eMIOS and eTPU ODIS connections

The following table lists the Output Disable (ODIS) connections between eMIOS and eTPU modules. The eMIOS modules' Cn[ODISSL] fields for the applicable channels use these connections.

**Table 34-2. eMIOS and eTPU ODIS connections**

| Source   |                       | Destination |                 | Description                                                                                                   |
|----------|-----------------------|-------------|-----------------|---------------------------------------------------------------------------------------------------------------|
| Instance | Pin                   | Instance    | Pin             |                                                                                                               |
| EMIOS_0  | emios_flag_out[16:19] | EMIOS_0     | emios_odis[3:0] | Connection from EMIOS_0 Channel Flag Out numbers 16, 17, 18, 19 to EMIOS_0 ODIS bits 3, 2, 1, 0, respectively |
| EMIOS_1  | emios_flag_out[16:19] | EMIOS_1     | emios_odis[3:0] | Connection from EMIOS_1 Channel Flag Out numbers 16, 17, 18, 19 to EMIOS_1 ODIS bits 3, 2, 1, 0, respectively |

*Table continues on the next page...*

**Table 34-2. eMIOS and eTPU ODIS connections (continued)**

| Source   |                       | Destination |                  | Description                                                                                                  |
|----------|-----------------------|-------------|------------------|--------------------------------------------------------------------------------------------------------------|
| Instance | Pin                   | Instance    | Pin              |                                                                                                              |
| EMIOS_0  | emios_flag_out[16:19] | ETPU_C      | etpu_odis_1[3:0] | Connection from EMIOS_0 Channel Flag Out numbers 16, 17, 18, 19 to ETPU_C ODIS bits 3, 2, 1, 0, respectively |
| EMIOS_1  | emios_flag_out[16:19] | ETPU_A      | etpu_odis_1[3:0] | Connection from EMIOS_1 Channel Flag Out numbers 16, 17, 18, 19 to ETPU_A ODIS bits 3, 2, 1, 0, respectively |
| EMIOS_1  | emios_flag_out[23:20] | ETPU_B      | etpu_odis_2[3:0] | Connection from EMIOS_1 Channel Flag Out numbers 23, 22, 21, 20 to ETPU_B ODIS bits 3, 2, 1, 0, respectively |

### 34.1.3.3 STAC server IDs

STAC server IDs are defined in [STAC server IDs](#).

### 34.1.3.4 eMIOS and DSPI connections

See [DSPI and eMIOS direct connections](#) and [DSPI connections with SIU, eTPU, and eMIOS modules](#).

### 34.1.3.5 eMIOS inputs with Glitch Filters

See [IGF interaction with other modules](#) for connections between eMIOS and Input Glitch Filters (IGFs).

### 34.1.3.6 eMIOS and eTPU signal passthrough from pins via IGFs

On this chip, the IGF modules mediate between some pins and the eMIOS and eTPU modules. After system reset, the IGF modules are in Configuration mode by default. This mode disables IGF output and prevents the signals from the pins from reaching the eMIOS and eTPU modules.

The signals affected by this situation appear in [IGF interaction with other modules](#).

To route an affected signal directly to an eMIOS or eTPU instance, program the applicable channel of the applicable IGF instance:

1. Ensure that IGF\_MCRn[MDIS] is 0 and that the IGF channel is disabled: IGF\_MCRn[FGEN] is 0.
2. Configure the rising and falling edges for bypass:
  - Rising edge: Write 00b to IGF\_MCRn[RFM].
  - Falling edge: Write 00b to IGF\_MCRn[FFM].
3. Enable the IGF channel: Write 1 to IGF\_MCRn[FGEN].

At the end of this sequence, the programmed filter enters Normal mode and passes through the affected signal.

## **34.2 Introduction**

### **34.2.1 Overview**

The configurable enhanced Modular Input/Output Subsystem (eMIOS) provides functionality to generate or measure time events. Its overall architecture resembles that of the MIOS timer.

The predecessor MIOS timer block provides a framework in which a set of sublocks with different timer functions are assembled to attend to the specific needs of an SoC. The eMIOS builds on this concept by using a Unified Channel module that provides a superset of the functionality of all the individual MIOS channels, while also providing a consistent user interface. This allows more flexibility as each Unified Channel can be programmed for different functions in different applications of the SoC. In addition, eMIOS architecture allows the use of Dedicated Channels which perform specific functions not included in MIOS inheritance.

The block diagram of the configurable eMIOS block is shown below.

**Figure 34-1. eMIOS full channel configuration using Unified Channels only (see Configuration section)**

### 34.2.2 Features

The eMIOS has the following features:

- Up to 32 channels chosen among Unified or Dedicated Channels, not necessarily numbered in a continuous sequence. (See Configuration information)
- Data registers of either 8-, 16-, 24-, or 32-bit width. (See Configuration information)
- Counter buses B, C, D, and E can be driven by Unified Channels 0, 8, 16, and 24, respectively. (See Configuration information)
- Counter bus A can be driven by Unified Channel 23 or by the external shared timer bus(Red-Line Client).
- Each channel has its own timebase, alternative to the counter buses.
- One global prescaler
- One prescaler per channel (CP)
- Timebases shared through the counter buses
- One STAC Client (STAC)
- Control and status bits grouped in separated registers
- Synchronization among timebases
- Shadow FLAG register
- State of the Unified Channels can be frozen for debug purposes

### **34.2.3 Modes of operation**

The Unified Channels can be configured to operate in the following modes:

- General-Purpose Input/Output (GPIO)
- Single-Action Input Capture (SAIC)
- Single-Action Output Compare (SAOC)
- Input Pulse-Width Measurement (IPWM)
- Input Period Measurement (IPM)
- Double-Action Output Compare (DAOC)
- Pulse/Edge Accumulation (PEA)
- Pulse/Edge Counting (PEC)
- Quadrature Decode (QDEC)
- Windowed Programmable Time Accumulation (WPTA)

- Modulus Counter (MC)
- Modulus Counter Buffered (MCB)
- Output Pulse-Width and Frequency Modulation (OPWFM)
- Output Pulse-Width and Frequency Modulation Buffered (OPWFMB)
- Center Aligned Output Pulse Width Modulation with Dead Time Insertion (OPWMC)
- Output Pulse-Width Modulation (OPWM)
- Output Pulse-Width Modulation Buffered (OPWMB)

These modes are described in [Unified Channel modes of operation](#).

Each channel can have a specific set of modes.

## 34.3 Memory map / register definition

### 34.3.1 Memory map

The overall address map organization is shown in the table below.

Whenever an access to either an absent register, absent channel, or reserved address space is performed, the transfer is terminated with an error.

**Table 34-3. eMIOS Memory Map**

| eMIOS[n] Base Address | Description                              |
|-----------------------|------------------------------------------|
| 0x000<br>0x003        | Module Configuration register (EMIOSMCR) |
| 0x004<br>0x007        | Global FLAG register (EMIOSGFLAG)        |
| 0x008<br>0x00B        | Output Update Disable (EMIOSOUDIS)       |
| 0x00C<br>0x00F        | Reserved                                 |
| 0x01F                 | Reserved                                 |
| 0x020<br>0x11F        | Channel 0 to Channel 7                   |
| 0x120<br>0x21F        | Channel 8 to Channel 15                  |

*Table continues on the next page...*

**Table 34-3. eMIOS Memory Map (continued)**

| eMIOS[n] Base Address | Description              |
|-----------------------|--------------------------|
| 0x220<br>0x31F        | Channel 16 to Channel 23 |
| 0x320<br>0x41F        | Channel 24 to Channel 31 |
| 0x420<br>0xFFF        | Reserved                 |

### 34.3.1.1 Unified channel memory map

Addresses of Unified Channel registers are specified as offsets from the channel's base address, otherwise the eMIOS base address is used as reference.

The following table describes the Unified Channel memory map.

**Table 34-4. Unified channel memory map**

| UC[n] Base Address                       | Description                         |
|------------------------------------------|-------------------------------------|
| UC[n]_BASE + 0x000                       | A register (EMIOSA[n])              |
| UC[n]_BASE + 0x004                       | B register (EMIOSB[n])              |
| UC[n]_BASE + 0x008                       | Counter register (EMIOSCNT[n])      |
| UC[n]_BASE + 0x00C                       | Control register (EMIOSC[n])        |
| UC[n]_BASE + 0x010                       | Status register (EMIOSS[n])         |
| UC[n]_BASE + 0x014                       | Alternate A register (EMIOSALTA[n]) |
| UC[n]_BASE + 0x018                       | Control 2 register (EMIOSC2[n])     |
| UC[n]_BASE + 0x01C to UC[n]_BASE + 0x01F | Reserved                            |

## 34.4 Control Memory Map and Registers

All control registers are 32 bits wide. This document illustrates the eMIOS with 24 Unified Channels and 24-bit wide data registers.

### eMIOS memory map

| Address offset (hex) | Register name                                   | Width (in bits) | Access | Reset value | Section/page                |
|----------------------|-------------------------------------------------|-----------------|--------|-------------|-----------------------------|
| 0                    | eMIOS Module Configuration Register (eMIOS_MCR) | 32              | R/W    | 0000_0000h  | <a href="#">34.4.1/1199</a> |

*Table continues on the next page...*

**eMIOS memory map (continued)**

| Address offset (hex) | Register name                                      | Width (in bits) | Access | Reset value | Section/ page               |
|----------------------|----------------------------------------------------|-----------------|--------|-------------|-----------------------------|
| 4                    | eMIOS Global FLAG Register (eMIOS_GFLAG)           | 32              | R      | 0000_0000h  | <a href="#">34.4.2/1201</a> |
| 8                    | eMIOS Output Update Disable register (eMIOS_OUDIS) | 32              | R/W    | 0000_0000h  | <a href="#">34.4.3/1201</a> |

**34.4.1 eMIOS Module Configuration Register (eMIOS\_MCR)**

The MCR register contains Global Control bits for the eMIOS block.

Address: 0h base + 0h offset = 0h

### 34.4.2 eMIOS Global FLAG Register (eMIOS\_GFLAG)

GFLAG is a read-only register that groups the FLAG bits from all channels. Each bit relates to one channel.

Address: 0h base + 4h offset = 4h

| Field           | Description                                                                                                                                                                                                                                                                                                                                                                                                           |
|-----------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–7<br>Reserved | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                              |
| 8–31<br>A       | Depending on the mode of operation, internal registers A1[ 0:23 ] or A2[ 0:23 ], used for matches and captures, can be assigned to address EMIOS_An. Both A1 and A2 are cleared by reset. The table in the EMIOS_Bn register description summarizes the EMIOS_An writing and reading accesses for all operation modes. Values not listed are reserved. For more information, see the “UC Modes of Operation” section. |

**34.5.2 eMIOS UC B register n (eMIOS\_Bn)**

This section describes the register for channels 0-7. For channels 16-23, see [eMIOS UC B register n \(eMIOS\\_Bn\)](#).

Depending on the mode of operation, internal registers B1[ 0:23 ] or B2[ 0:23 ] can be assigned to address EMIOS\_Bn. Both B1 and B2 are cleared by reset. The table below summarizes the EMIOS\_Bn writing and reading accesses for all operation modes. Values not listed are reserved. For more information see the “UC Modes of Operation” section.

Depending on the channel configuration, it may have an EMIOS\_B register or not. EMIOS\_B register is required for the following modes: DAOC, IPM, IPWM, OPWM, OPWMB, OPWFM , OPWFMB, OPWMC, OPWMCB, MC, MCB, PEA, PEC, WPTA.

The following table summarizes the EMIOS\_An, EMIOS\_Bn, and EMIOS\_ALTAn writing and reading accesses for all operation modes. Values not listed are reserved. For more information, see the “UC Modes of Operation” section.

**Table 34-15. EMIOS\_An, EMIOS\_Bn and EMIOS\_ALTAn values assignment**

| Operation mode    | Register access |      |        |      |           |          |
|-------------------|-----------------|------|--------|------|-----------|----------|
|                   | Write           | Read | Write  | Read | Alt write | Alt read |
| GPIO              | A1, A2          | A1   | B1, B2 | B1   | A2        | A2       |
| SAIC <sup>1</sup> | –               | A2   | B2     | B2   | –         | –        |
| SAOC <sup>1</sup> | A2              | A1   | B2     | B2   | –         | –        |
| IPWM              | –               | A2   | –      | B1   | –         | –        |
| IPM               | –               | A2   | –      | B1   | –         | –        |
| DAOC              | A2              | A1   | B2     | B1   | –         | –        |
| PEA               | A1              | A2   | –      | B1   | –         | –        |
| PEC <sup>1</sup>  | A1              | A1   | B1     | B1   | –         | A2       |
| QDEC <sup>1</sup> | A1              | A1   | B2     | B2   | –         | –        |
| WPTA              | A1              | A1   | B1     | B1   | –         | A2       |

*Table continues on the next page...*

**Table 34-15. EMIOS\_An, EMIOS\_Bn and EMIOS\_ALTAn values assignment (continued)**

| Operation mode   | Register access |      |       |      |           |          |
|------------------|-----------------|------|-------|------|-----------|----------|
|                  | Write           | Read | Write | Read | Alt write | Alt read |
| MC <sup>1</sup>  | A2              | A1   | B2    | B2   | —         | —        |
| OPWFM            | A2              | A1   | B2    | B1   | —         | —        |
| OPWMC            | A2              | A1   | B2    | B1   | —         | —        |
| OPWM             | A2              | A1   | B2    | B1   | —         | —        |
| OPWMT            | A2              | A1   | B2    | B1   | A2        | A2       |
| MCB <sup>1</sup> | A2              | A1   | B2    | B1   | —         | —        |
| OPWFMB           | A2              | A1   | B2    | B1   | —         | —        |
| OPWMCB           | A2              | A1   | B2    | B1   | —         | —        |
| OPWMB            | A2              | A1   | B2    | B1   | —         | —        |

1. In these modes, the register EMIOS\_Bn is not used, but B2 can be accessed.

Address: 0h base + 24h offset + (32d × i), where i=0d to 7d

### eMIOS\_Bn field descriptions

| Field           | Description                                                                                              |
|-----------------|----------------------------------------------------------------------------------------------------------|
| 0–7<br>Reserved | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0. |
| 8–31<br>B       | See text above register figure.                                                                          |

1. In these modes, the register EMIOS\_Bn is not used, but B2 can be accessed.

### 34.5.3 eMIOS CNT register n (eMIOS\_CNTn)

This section describes the register for channels 0-7. For channels 16-23, see [eMIOS CNT register n \(eMIOS\\_CNTn\)](#).

When GPIO mode is selected or the channel is frozen, the EMIOS\_CNTn register is read/write. For all others modes, the EMIOS\_CNTn is a read-only register. When entering some operation modes, this register is automatically cleared (refer to the “UC Modes of Operation” section for details).

EMIOS\_CNTn register is required for the following modes:

- OPWFM

Unified Channels Memory Map and Registers

- OPWFMB
- OPWMC
- OPWMCB
- PEA
- PEC
- WPTA
- QDEC
- MC
- MCB

For other modes, the internal counter is not used. Therefore, depending on the modes available in a channel, the internal counter may be absent.

Address: 0h base + 28h offset + (32d × i), where i=0d to 7d

eMIOS\_CNTn field descriptions

| Field           | Description                                                                                              |
|-----------------|----------------------------------------------------------------------------------------------------------|
| 0–7<br>Reserved | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0. |
| 8–31<br>C       | The C field contains the value of the internal counter.                                                  |

34.5.4 eMIOS UC Control register n (eMIOS\_Cn)

This section describes the register for channels 0-7. For channels 16-23, see [eMIOS UC Control register n \(eMIOS\\_Cn\)](#).

The UC Control register gathers several read/write control bits affecting the UC operation conditions.

NOTE

This register does not include a FORCMB bit for Channel Types A and C.

Address: 0h base + 2Ch offset + (32d × i), where i=0d to 7d

|       | 1. Not all modes of operation are supported. See the configuration information for details.<br>2. b = adjust parameters for the mode of operation. Refer to “UC Modes of Operation” section for details. |                                                                                   |

1. Filter latency (the difference in time between the input and the response) is 3 clock edges.
2. The input signal is synchronized before arriving to the digital filter.
3. Not all devices support all counter buses. See the Device Configuration chapter for details.
4. Not all modes of operation are supported. See the configuration information for details.
5. b = adjust parameters for the mode of operation. Refer to “UC Modes of Operation” section for details.

**34.5.5 eMIOS UC Status register n (eMIOS\_Sn)**

This section describes the register for channels 0-7. For channels 16-23, see [eMIOS UC Status register n \(eMIOS\\_Sn\)](#).

The UC Status register EMIOS\_Sn gathers bits reflecting the status of the UC input/output signals and the overflow condition of the internal counter.

Address: 0h base + 30h offset + (32d × i), where i=0d to 7d

**34.5.6 eMIOS Alternate Address register n (eMIOS\_ALTAn)**

This section describes the register for channels 0-7. For channels 16-23, see [eMIOS Alternate Address register n \(eMIOS\\_ALTAn\)](#).

The eMIOS\_ALTAn register provides an alternate address to access A2 channel registers in restricted modes (GPIO, PEC, WPTA )only. In modes where the function of eMIOS\_ALTAn register is not specified, any write access is ignored and any read access returns unspecified data. If eMIOS\_An register is used along with eMIOS\_ALTAn, both A1 and A2 registers can be accessed in these modes. The table in the eMIOS\_Bn register's description summarizes the EMIOS\_ALTAn writing and reading accesses for all EMIOS\_ALTAn operation modes. See the “General purpose Input/Output mode (GPIO) Mode” section, the “Pulse/Edge Counting (PEC) Mode” section, the “Windowed Programmable Time Accumulation (WPTA) Mode” section for a more detailed description of the use of eMIOS\_ALTAn register.

**34.5.7 eMIOS UC A register n (eMIOS\_An)**

This section describes the register for channels 16-23. For channels 0-7, see [eMIOS UC A register n \(eMIOS\\_An\)](#).

Address: 0h base + 220h offset + (32d × i), where i=0d to 7d

**eMIOS\_An field descriptions**

| Field           | Description                                                                                                                                                                                                                                                                                                                                                                                                           |
|-----------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–7<br>Reserved | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                              |
| 8–31<br>A       | Depending on the mode of operation, internal registers A1[ 0:23 ] or A2[ 0:23 ], used for matches and captures, can be assigned to address EMIOs_An. Both A1 and A2 are cleared by reset. The table in the EMIOs_Bn register description summarizes the EMIOs_An writing and reading accesses for all operation modes. Values not listed are reserved. For more information, see the “UC Modes of Operation” section. |

**34.5.8 eMIOS UC B register n (eMIOS\_Bn)**

This section describes the register for channels 16-23. In all other respects, this register is identical to the register for channels 0-7. See that register's description: [eMIOS UC B register n \(eMIOS\\_Bn\)](#).

Address: 0h base + 224h offset + (32d × i), where i=0d to 7d

1. Filter latency (the difference in time between the input and the response) is 3 clock edges.
2. The input signal is synchronized before arriving to the digital filter.
3. Not all devices support all counter buses. See the Device Configuration chapter for details.
4. Not all modes of operation are supported. See the configuration information for details.
5. b = adjust parameters for the mode of operation. Refer to “UC Modes of Operation” section for details.

**34.5.11 eMIOS UC Status register n (eMIOS\_Sn)**

This section describes the register for channels 16-23. For channels 0-7, see [eMIOS UC Status register n \(eMIOS\\_Sn\)](#).

The UC Status register EMIOS\_Sn gathers bits reflecting the status of the UC input/output signals and the overflow condition of the internal counter.

Address: 0h base + 230h offset + (32d × i), where i=0d to 7d

**34.6 Functional Description**

The eMIOS provides independent channels (Unified) that can be configured and accessed by a host MCU. Up to five time bases can be shared by the channels.

The eMIOS module is based on a multi-bus timer architecture in which several timer channels are used to drive counter buses that are shared among the channels. Up to five timebases can be shared by the channels through five counter buses (counter bus A or F, B, C, D and E) and each channel can generate its own timebase. There are five counter buses in the module: one global counter bus, shared by all channels and selectable among time bases A or F, and four local counter buses (B, C, D, and E), each one dedicated to a slice of 8 channels. Counter bus A is referred to as the global counter bus. Counter buses B, C, D, and E are the local counter buses.

The eMIOS counter buses are driven by channels in specific locations. Global counter bus A is driven by the channel in channel slot [23].. Counter buses B, C, D, and E are driven by channels in slots 0, 8, 16, and 24, respectively. Counter bus A or F drives all channels. Counter bus B drives channels in slots from 0 through 7. Counter bus C drives channels in slots from 8 through 15. Counter bus D drives channels in slots from 16 through 23. Counter bus E drives channels from 24 through 31.

The eMIOS block is reset asynchronously. All registers are cleared on reset.

The following figure shows an eMIOS block configured with a mix of Unified Channels. In this configuration example, each one of the channels can be driven by the respective local bus—B for the [7:0] slice and D for the [23:16] slice—or by the global counter bus A. Note that there are Unified Channels with no external pin associated. These channels are used to trigger internal SoC signals such as interrupt requests or DMA transfer requests. Since the channel flags are also connected to the block top-level pins, they can be used as trigger signals for other blocks at chip level.

**Figure 34-113. eMIOS example configuration using Unified Channels**

## 34.6.1 Unified Channel (UC)

Figure 34-114 shows the Unified Channel block diagram. Each Unified Channel consists of the following:

- A counter bus selector, which selects the timebase to be used by the channel for all timing functions
- A programmable clock prescaler
- Two double-buffered data registers, A and B, that allow up to two input capture and/or output compare events to occur before software intervention is needed
- Two comparators (equal only), A and B, that compare the selected counter bus with the value in the data registers

- An internal counter, which can be used as a local time base or to count input events
- Programmable input filter, which ensures that only valid pin transitions are received by channel
- Programmable input edge detector, which detects the rising, falling, or either edge
- An output flip-flop, which holds the logic level to be applied to the output pin
- eMIOS Status and Control register
- An Output Disable Input selector, which selects the Output Disable Input signal that will be used as output disable

**Figure 34-114. Unified Channel block diagram**

Figure 34-115 shows both the Unified Channel control and datapath block diagrams. The control sub-block is responsible for the generation of signals to control the multiplexers in the datapath sub-block. Each mode is implemented by a dedicated logic independent from others modes, thus allowing to optimize the logic by disabling the mode and therefore its associated logic. Targeting the logic optimization, a set of registers is shared by the modes thus providing sequential events to be stored.

The datapath block provides the channel A and B registers, the internal timebase and comparators. Multiplexers select the input of comparators and data for the registers inputs, thus configuring the datapath to implement the channel modes. The outputs of the A and B comparators are connected to the uc\_ctrl control block.

Figure 34-115. Unified Channel control and datapath block diagrams

### 34.6.1.1 Unified Channel modes of operation

The mode of operation of the Unified Channel is determined by the mode select bits `MODE[0:6]` in the `EMIOS_C_n` register.

When entering an output mode (except for GPIO mode), the output flip-flop is set to the disabled state according to `EMIOSCn[ODIS]`.

As the internal counter, `EMIOSCNTn`, runs in all modes (except for GPIO mode) and can be used as a timebase if the resource is not used in the current mode.

In order to provide smooth waveform generation even when A and B registers are immediately changed, it is available with the MCB, OPWFMB, OPWMB and OPWFMB modes. In these modes, A and B registers are double buffered. They are presented in separate sections because there are several basic differences between these and each corresponding nonbuffered mode.

#### 34.6.1.1.1 General-Purpose Input/Output (GPIO) mode

In GPIO mode, all input capture and output compare functions of the Unified Channel are disabled, and the internal counter (EMIOSCNTn register) is cleared and disabled. All control bits remain accessible. In order to prepare the UC for a new operation mode, writing to registers EMIOSAn or EMIOSBn stores the same value in registers A1/A2 or B1/B2, respectively. Writing to the EMIOSALTAn register stores a value only in register A2.

MODE[6] bit selects between input (MODE[6] = 0) and output (MODE[6] = 1) modes.

When changing MODE[0:6], the application software must first enter GPIO mode to reset the Unified Channel's internal functions properly. Failure to do this could lead to invalid and unexpected output compare or input capture results or the FLAGs being set incorrectly.

In GPIO input mode (MODE[0:6] = 0000000), FLAG generation is determined according to EDPOL and EDSEL bits and the input pin status can be determined by reading the UCIN bit.

In GPIO output mode (MODE[0:6] = 0000001), the Unified Channel is used as a single output port pin and the value of the EDPOL bit is permanently transferred to the output flip-flop.

#### 34.6.1.1.2 Single Action Input Capture (SAIC) Mode

In SAIC mode (MODE[0:6]=0000010), when a triggering event occurs on the input pin, the value on the selected time base is captured into register A2. The FLAG bit is set along with the capture event to indicate that an input capture has occurred. Register EMIOSA[n] returns the value of register A2. As soon as the SAIC mode is entered coming out from GPIO mode the channel is ready to capture events. The events are captured as soon as they occur thus reading register A always returns the value of the latest captured event. Subsequent captures are enabled with no need of further reads from EMIOSA[n] register. The FLAG is set at any time a new event is captured.

The input capture is triggered by a rising, falling or either edges in the input pin, as configured by EDPOL and EDSEL bits in EMIOSC[n] register.

Figure 34-116 and Figure 34-117 show how the Unified Channel can be used for input capture.

**Figure 34-116. Single Action Input Capture with rising edge triggering example**

**Figure 34-117. Single Action Input Capture with both edges triggering example**

### 34.6.1.1.3 Single Action Output Compare (SAOC) Mode

In SAOC mode (MODE[0:6]=0000011) a match value is loaded in register A2 and then immediately transferred to register A1 to be compared with the selected time base. When a match occurs, the EDSEL bit selects whether the output flip-flop is toggled or the value in EDPOL is transferred to it. Along with the match the FLAG bit is set to indicate that the output compare match has occurred. Writing to register EMIOSA[n] stores the value in register A2 and reading to register EMIOSA[n] returns the value of register A1.

An output compare match can be simulated in software by setting the FORCMA bit in EMIOSC[n] register. In this case, the FLAG bit is not set.

When SAOC mode is entered coming out from GPIO mode, the output flip-flop is set to the complement of the EDPOL bit in the EMIOSC[n] register.

Counter bus can be either internal or external and is selected through BSL[0:1] bits.

Figure 34-118 and Figure 34-119 show how the Unified Channel can be used to perform a single output compare with EDPOL value being transferred to the output flip-flop and toggling the output flip-flop at each match, respectively. Note that once in SAOC mode the matches are enabled thus the desired match value on register A1 must be written before the mode is entered. A1 register can be updated at any time thus modifying the match value which will reflect in the output signal generated by the channel. Subsequent matches are enabled with no need of further writes to EMIOSA[n] register. The FLAG is set at the same time a match occurs (see Figure 34-120).

### Note

The channel internal counter in SAOC mode is free-running. It starts counting as soon as the SAOC mode is entered.

**Figure 34-118. SAOC example with EDPOL value being transferred to the output flip-flop**

**Figure 34-119. SAOC example toggling the output flip-flop**

**Figure 34-120. SAOC example with flag behavior**

#### 34.6.1.1.4 Input Pulse Width Measurement (IPWM) Mode

The IPWM mode (MODE[0:6]=0000100) allows the measurement of the width of a positive or negative pulse by capturing the leading edge on register B1 and the trailing edge on register A2. Successive captures are done on consecutive edges of opposite polarity. The leading edge sensitivity (i.e., pulse polarity) is selected by EDPOL bit in the EMIOSC[n] register. Registers EMIOSA[n] and EMIOSB[n] return the values in register A2 and B1, respectively.

The capture function of register A2 remains disabled until the first leading edge triggers the first input capture on register B2. When this leading edge is detected, the count value of the selected time base is latched into register B2; the FLAG bit is not set. When the trailing edge is detected, the count value of the selected time base is latched into register A2 and, at the same time, the FLAG bit is set and the content of register B2 is transferred to register B1 and to register A1.

If subsequent input capture events occur while the corresponding FLAG bit is set, registers A2, B1 and A1 will be updated with the latest captured values and the FLAG will remain set. Registers EMIOSA[n] and EMIOSB[n] return the value in registers A2 and B1, respectively.

In order to guarantee coherent access, reading EMIOSA[n] forces B1 be updated with the content of register A1. At the same time transfers between B2 and B1 are disabled until the next read of EMIOSB[n] register. Reading EMIOSB[n] register forces B1 be updated with A1 register content and re-enables transfers from B2 to B1, to take effect at the next trailing edge capture. Transfers from B2 to A1 are not blocked at any time.

The input pulse width is calculated by subtracting the value in B1 from A2.

The following figure shows how the Unified Channel can be used for input pulse width measurement.

**Figure 34-121. Input Pulse Width Measurement example**

The following figure shows the A1 and B1 updates when EMIOSA[n] and EMIOB[n] register reads occur. Note that A1 register has always coherent data related to A2 register. Note also that when EMIOSA[n] read is performed B1 register is loaded with A1 register content. This guarantee that the data in register B1 has always the coherent data related to the last EMIOSA[n] read. The B1 register updates remains locked until EMIOB[n] read occurs. If EMIOSA[n] read is performed B1 is updated with A1 register content even if B1 update is locked by a previous EMIOSA[n] read operation.

**Figure 34-122. B1 and A1 updates at EMIOSA[n] and EMIOB[n] reads**

Reading EMIOS\_A\_n followed by EMIOS\_B\_n always provides coherent data. If coherent data is not required for any reason, the sequence of reads should be inverted, therefore EMIOB[n] should be read prior to EMIOSA[n] register. Note that even in this case B1 register updates will be blocked after EMIOSA[n] read, thus a second EMIOB[n] is required in order to release B1 register updates.

### 34.6.1.1.5 Input Period Measurement (IPM) Mode

The IPM mode (MODE[0:6]=0000101) allows the measurement of the period of an input signal by capturing two consecutive rising edges or two consecutive falling edges. Successive input captures are done on consecutive edges of the same polarity. The edge polarity is defined by the EDPOL bit in the EMIOSC[n] register.

#### Note

The input signal must have at least four system clock cycles period in order to be properly captured by the synchronization logic at the channel input even if the input filter is in by-pass mode.

When the first edge of selected polarity is detected, the selected time base is latched into the registers A2 and B2, and the data previously held in register B2 is transferred to register B1. On this first capture the FLAG line is not set, and the values in registers B1 is meaningless. On the second and subsequent captures, the FLAG line is set and data in register B2 is transferred to register B1.

When the second edge of the same polarity is detected, the counter bus value is latched into registers A2 and B2, the data previously held in register B2 is transferred to data register B1 and to register A1. The FLAG bit is set to indicate the start and end points of a complete period have been captured. This sequence of events is repeated for each subsequent capture. Registers EMIOSA[n] and EMIOSB[n] return the values in register A2 and B1, respectively.

In order to allow coherent data, reading EMIOSA[n] forces A1 content be transferred to B1 register and disables transfers between B2 and B1. These transfers are disabled until the next read of the EMIOSB[n] register. Reading EMIOSB[n] register forces A1 content to be transferred to B1 and re-enables transfers from B2 to B1, to take effect at the next edge capture.

The input pulse period is calculated by subtracting the value in B1 from A2.

The following figure shows how the Unified Channel can be used for input period measurement.

Figure 34-123. Input Period Measurement example

Figure 34-124 describes the A1 and B1 register updates when EMIOSA[n] and EMIOSB[n] read operations are performed. When EMIOSA[n] read occurs the content of A1 is transferred to B1 thus providing coherent data in A2 and B1 registers. Transfers from B2 to B1 are then blocked until EMIOSB[n] is read. After EMIOSB[n] is read, register A1 content is transferred to register B1 and the transfers from B2 to B1 are re-enabled to occur at the transfer edges, which is the leading edge in the following example figure.

Figure 34-124. A1 and B1 updates at EMIOSA[n] and EMIOSB[n] reads

#### 34.6.1.1.6 Double Action Output Compare (DAOC) Mode

In the DAOC mode, the leading and trailing edges of the variable pulse width output are generated by matches occurring on comparators A and B. There is no restriction concerning the order in which A and B matches occur.

When the DAOC mode is entered, coming out from GPIO mode both comparators are disabled and the output flip-flop is set to the complement of the EDPOL bit in the EMIOSC[n] register.

Data written to A2 and B2 are transferred to A1 and B1, respectively, on the next system clock cycle if OU[n] bit of EMIOSOUDIS register is cleared (see ). The transfer is blocked if OU[n] bit is set. Comparator A is enabled only after the transfer to A1 register occurs and is disabled on the next A match. Comparator B is enabled only after the transfer to B1 register occurs and is disabled on the next B match. Comparators A and B are enabled and disabled independently.

The output flip-flop is set to the value of EDPOL when a match occurs on comparator A and to the complement of EDPOL when a match occurs on comparator B.

MODE[6] controls if the FLAG is set on both matches (MODE[0:6]=0000111) or just on the B match (MODE[0:6]=0000110). FLAG bit assertion depends on comparator enabling.

If subsequent enabled output compares occur on registers A1 and B1, pulses will continue to be generated, regardless of the state of the FLAG bit.

At any time, the FORCMA and FORCMB bits allow the software to force the output flip-flop to the level corresponding to a comparison event in comparator A or B, respectively. Note that the FLAG bit is not affected by these forced operations.

### **Note**

If both registers (A1 and B1) are loaded with the same value, the B match prevails concerning the output pin state (output flip-flop is set to the complement of EDPOL), the FLAG bit is set and both comparators are disabled.

The following two tables show how the Unified Channel can be used to generate a single output pulse with FLAG bit being set on the second match or on both matches, respectively.

**Figure 34-125. Double Action Output Compare with FLAG set on the second match, MODE[0] bit is 0**

**Figure 34-126. Double Action Output Compare with FLAG set on both matches, MODE[0] bit is 1**

Figure 34-127. DAOC with transfer disabling example

### 34.6.1.1.7 Pulse/Edge Accumulation (PEA) Mode

The PEA mode returns the time taken to detect a desired number of input events. MODE[6] bit selects between continuous or single shot operation.

After writing to register A1, the internal counter is cleared on the first input event, ready to start counting input events and the selected timebase is latched into register B2. On the match between the internal counter and register A1, a counter bus capture is triggered to register A2 and B2. The data previously held in register B2 is transferred to register B1 and the FLAG bit is set to indicate that an event has occurred. The desired time interval can be determined by subtracting register B1 from A2. Registers EMIOSA[n] and EMIOSB[n] return the values in register A2 and B1, respectively.

As part of the coherency mechanism, reading EMIOSA[n] disables transfers from B2 to B1. These transfers are disabled until the next read of the EMIOS\_B\_n register. Reading the EMIOSB[n] register re-enables transfers from B2 to B1, to take effect at the next transfer event, as described above. <sup>1</sup>

In order to have coherent data in continuous mode of operation the following steps should be performed, assuming FLAG is initially cleared:

1. If B1 was not updated due to B2 to B1 transfer being disabled after reading register EMIOS\_A\_n, further EMIOS\_A\_n] and EMIOS\_B\_n reads will not return coherent data until a new bus capture is triggered to registers A2 and B2. This capture event is indicated by the channel FLAG being asserted. If enabled, the FLAG also generates an interrupt.

1. Wait for FLAG assertion;
2. Read EMIOSA[n] register;
3. Read EMIOSB[n] register;
4. Clear FLAG bit;
5. Return to step 1.

Accumulation cycles may be lost if the read is not performed in a timely manner. Whenever Overrun bit is asserted it means that one or more cycles have been lost.

Triggering of the counter clock (input event) is done by a rising or falling edge or both edges on the input pin. The polarity of the triggering edge is selected by the EDSEL and EDPOL bits in EMIOS\_C\_n register.

For continuous operation mode (MODE[6] cleared, MODE[0:6]=0001000), the counter is cleared on the next input event after a FLAG generation and continues to operate as described above.

For single shot operation (MODE[6] set, MODE[0:6]=0001001), the counter is not cleared or incremented after a FLAG generation, until a new writing operation to register A is performed.

Figure 34-128 and Figure 34-129 show how the Unified Channel can be used for continuous and single shot pulse/edge accumulation mode.

**Figure 34-128. Pulse/Edge Accumulation continuous mode example (MODE[6] bit is 0b)**

**Figure 34-129. Pulse/Edge Accumulation single-shot mode example (MODE[6] bit is 1b)**

### 34.6.1.1.8 Pulse/Edge Counting (PEC) Mode

The PEC mode returns the amount of pulses or edges detected on the input for a desired time window. MODE[6] bit selects between continuous or single shot operation.

Triggering of the internal counter is done by a rising or falling edge or both edges on the input signal. The polarity and the triggering edge is selected by EDSEL and EDPOL bits in EMIOSC[n] register.

Register A1 holds the start time and register B1 holds the stop time for the time window. After writing to register A1, when a match occur between comparator A and the selected timebase, the internal counter is cleared and it is ready to start counting input events. When the time base matches comparator B, the internal counter is disabled and its content is transferred to register A2. At the same time the FLAG bit is set. Reading registers EMIOSCNT[n] or A2 returns the amount of detected pulses.

For continuous operation (MODE[6] cleared, MODE[0:6]=0001010), the next match between comparator A and the selected time base clears the internal counter and counting is enabled again. In order to guarantee coherent measurements when reading EMIOSCNT[n] after the FLAG is set, the software must check if the time base value is out of the time interval defined by registers A1 and B1. Alternatively register A2 always holds the latest available measurement providing coherent data at any time after the first FLAG had occurred. This register is addressed by the alternate address EMIOSALTA[n].

For single shot operation (MODE[6] set, MODE[0:6]=0001011), the next match between comparator A and the selected time base has no effect, until a new write to register A is performed. The EMIOSCNT content is also transferred to register A2 when a match in the B comparator occurs.

Figure 34-130 and Figure 34-131 show how the Unified Channel can be used for continuous or single shot pulse/edge counting mode.

**Figure 34-130. Pulse/Edge Counting continuous mode example**

**Figure 34-131. Pulse/Edge Counting single-shot mode example**

### 34.6.1.1.9 Quadrature Decode (QDEC) Mode

Quadrature decode mode uses UC[n] operating in QDEC mode and the input programmable filter (IPF) from UC[n-1]. Note that UC[n-1] can be configured, at the same time, to an operation mode that does not use I/O pins, such as MC mode (modulus counter). The connection among the UCs is circular, i.e., when UC[0] is running in QDEC mode, the input programmable filter from UC[23] is being used, for the case of a 24-channel configuration.

This mode generates a FLAG every time the internal counter matches A1 register. The internal counter is automatically selected and is not cleared when entering this mode.

MODE[6] bit selects which type of encoder will be used: *count & direction* encoder or *phase\_A* and *phase\_B* encoders.

When operating with *count and direction* encoder (MODE[6] cleared), UC[n] input pin must be connected to the *direction* signal and UC[n-1] input pin must be connected to the *count* signal of the quadrature encoder. UC[n] EDPOL bit selects count direction according to *direction* signal and UC[n-1] EDPOL bit selects if the internal counter is clocked by the rising or falling edge of the *count* signal.

When operating with *phase\_A* and *phase\_B* encoder (MODE[6] set), UC[n] input pin must be connected to the *phase\_A* signal and UC[n-1] input pin must be connected to the *phase\_B* signal of the quadrature encoder. EDPOL bit selects the count direction according to the phase difference between *phase\_A* and *phase\_B* signals.

Figure 34-132 and Figure 34-133 show two Unified Channels configured to quadrature decode mode for *count & direction* encoder and *phase\_A* and *phase\_B* encoders, respectively.

**Figure 34-132. Quadrature Decode mode example with *count and direction* encoder**

**Figure 34-133. Quadrature Decode mode example with *phase\_A* and *phase\_B* encoder**

#### 34.6.1.1.10 Windowed Programmable Time Accumulation (WPTA) Mode

The WPTA mode (MODE[0:6]=0001110) accumulates the sum of the total high time or low time of an input signal over a programmable interval (time window).

The prescaler bits UCPRE[0:1] in EMIOSC[n] register define the increment rate of the internal counter.

Register A1 holds the start time and register B1 holds the stop time of the programmable time interval. When a match occurs between register A and the selected timebase, the internal counter is cleared and it is ready to start counting. The internal counter is used as a time accumulator, i.e., it counts up when the input signal has the same polarity of EDPOL bit in EMIOSC[n] register and does not count otherwise. When a match occurs in comparator B, the internal counter is disabled regardless of the input signal polarity and the FLAG bit is set. At the same time the content of EMIOSCNT[n] is transferred to register A2. Reading registers EMIOSCNT[n] or A2 returns the high or low time of the input signal.

Note that EMIOSCNT[n] is stable only outside the time window defined from A1 to B1 matches, otherwise its content reflects a count in progress and not the final value. Alternatively to EMIOSCNT register A2 returns the latest available measurement. Since this register is updated only at comparator B matches it always contains stable and up-to-date data. In this mode this register is accessible through the alternate register address EMIOSALTA[n].

The following figure shows how the Unified Channel can be used to accumulate high time.

Timing diagram for the EMIOSCNT module. The diagram shows the relationship between the input signal, the time accumulator (EMIOSCNT), and the selected counter bus.

The input signal is shown as a square wave. The time accumulator (EMIOSCNT) is shown as a sawtooth waveform that increments during the A1 Match period and resets at the B1 Match.

The selected counter bus is shown as a series of values: 0x000100, 0x001500, 0x003000, and 0x004200.

The diagram also shows the A1 value, B1 value, and A2 value (A2 ← EMIOSCNT[n]) at various points in time.

Notes:

1. After the input filter
2. EMIOSA[n] = A1
3. EMIOSB[n] = B1
4. EMIOSALTA[n] = A2

- External clock is selected if MODE[0] is set. In this case the internal counter clears as soon as the match signal occurs. The channel FLAG is set at the same time the match occurs. Note that by having the internal counter cleared as soon as the match occurs and incremented at the next input event a shorter zero count is generated. See [Figure 34-160](#) and [Figure 34-161](#).
- Internal clock source is selected if MODE[0] is cleared. In this case the counter clears as soon as the match signal occurs. The channel FLAG is set at the same time the match occurs. At the next prescaler tick after the match the internal counter remains at zero and only resumes counting on the following tick. See [Figure 34-160](#) and [Figure 34-162](#).
- Internal counter clearing on match end (MODE[0:6]=001001b)
  - External clock is selected if MODE[0] is set. In this case the internal counter clears when the match signal is asserted and the input event occurs. The channel FLAG is set at the same time the counter is cleared. See [Figure 34-160](#) and [Figure 34-163](#).
  - Internal clock source is selected if MODE[0] is cleared. In this case the internal counter clears when the match signal is asserted and the prescaler tick occurs. The channel FLAG is set at the same time the counter is cleared. See [Figure 34-160](#) and [Figure 34-163](#).

### Note

If internal clock source is selected and the prescaler of the internal counter is set to 1 the MC mode behaves the same way even in Clear on Match Start or Clear on Match End sub-modes.

When in up/down count mode (MODE[0:6]=00101bb), a match between the internal counter and register A1 sets the FLAG and changes the counter direction from increment to decrement. A match between register B1 and the internal counter changes the counter direction from decrement to increment and sets the FLAG only if MODE[5] bit is set.

Only values different than 0x0 must be written at A register. Loading 0x0 leads to unpredictable results.

Updates on register A or counter in MC mode may cause loss of match in the current cycle if the transfer occurs near the match. In this case, the counter may rollover and resume operation in the next cycle.

Register B2 has no effect in MC mode. Nevertheless, register B2 can be accessed for reads and writes by addressing EMIOSB.

The following two figures show how the Unified Channel can be used as modulus counter in up mode and up/down mode, respectively.

**Figure 34-135. Modulus Counter up mode example (MODE[4] bit is 0)**

**Figure 34-136. Modulus Counter up/down mode example (MODE[4] bit is 1)**

## 34.6.1.1.12 Modulus Counter Buffered (MCB) Mode

The MCB mode provides a time base which can be shared with other channels through the internal counter buses. Register A1 is double buffered thus allowing smooth transitions between cycles when changing A2 register value on the fly. Register A1 is updated at the cycle boundary, which is defined as when the internal counter transitions to 0x1.

The internal counter values operates within a range from 0x1 up to register A1 value. If when entering MCB mode coming out from GPIO mode the internal counter value is not within that range then the A match will not occur causing the channel internal counter to wrap at the maximum counter value which is 0xff\_ffff for a 24-bit counter. After the counter wrap occurs it returns to 0x1 and resume normal MCB mode operation. Thus in order to avoid the counter wrap condition make sure its value is within the 0x1 to register A1 value range when the MCB mode is entered.

MODE[6] bit selects internal clock source if cleared or external if set. When external clock is selected the input channel pin is used as the channel clock source. The active edge of this clock is defined by EDPOL and EDSEL bits in the EMIOSC[n] channel register.

When entering in MCB mode, if up counter is selected by MODE[4]=0 (MODE[0:6]=101000b), the internal counter starts counting from its current value to up direction until A1 match occurs. The internal counter is set to 0x1 when its value matches A1 value and a clock tick occurs (either prescaled clock or input pin event).

If up/down counter is selected by setting MODE[4]=1, the counter changes direction at A1 match and counts down until it reaches the value 0x1. After it has reached 0x1 it is set to count in up direction again. Register B1 is used to generate a match in order to set the internal counter in up-count direction if up/down mode is selected. Register B1 cannot be changed while this mode is selected.

Note that differently from the MC mode, the MCB mode counts between 0x1 and A1 register value. Only values greater than 0x1 must be written at register A1. Loading values other than those leads to unpredictable results. The counter cycle period is equal to A1 value in up counter mode. If in up/down counter mode the period is defined by the expression:  $(2 * A1) - 2$ .

Figure 34-137 describes the counter cycle for several A1 values. Register A1 is loaded with A2 register value at the cycle boundary. Thus any value written to A2 register within cycle **n** will be updated to A1 at the next cycle boundary and therefore will be used on cycle **n+1**. The cycle boundary between cycle **n** and cycle **n+1** is defined as when the internal counter transitions from A1 value in cycle **n** to 0x1 in cycle **n+1**. Note that the FLAG is generated at the cycle boundary and has a synchronous operation, meaning that it is asserted one system clock cycle after the FLAG set event.

**Figure 34-137. Modulus Counter Buffered (MCB) Up Count mode**

Figure 34-138 describes the MCB in up/down counter mode (MODE[0:6]=10101bb). Register A1 is updated at the cycle boundary. If A2 is written in cycle *n*, this new value will be used in cycle *n+1* for A1 match. Flags are generated only at A1 match start if MODE[5] is 0. If MODE[5] is set to 1 flags are also generated at the cycle boundary.

**Figure 34-138. Modulus Counter Buffered (MCB) Up/Down Mode**

The figure below describes in more detail, the register A1 update process in up counter mode. The A1 load signal is generated at the last system clock period of a counter cycle. Thus, A1 is updated with A2 value at the same time that the counter (EMIOSCNT[n]) is loaded with 0x1. The load signal pulse has the duration of one system clock period. If A2 is written within cycle *n* its value is available at A1 at the first clock of cycle *n+1* and the new value is used for match at cycle *n+1*. The update disable bits OU[n] of EMIOSOUDIS register can be used to control the update of this register, thus allowing to delay the A1 register update for synchronization purposes.

**Figure 34-139. MCB Mode Register A1 Update in Up Counter Mode**

The figure below describes the register A1 update in up/down counter mode. Note that A2 can be written at any time within cycle **n** in order to be used in cycle **n+1**. Thus A1 receives this new value at the next cycle boundary. Note that the update disable bits **OU[n]** of **EMIOSOUDIS** register can be used to disable the update of register A1.

**Figure 34-140. MCB Mode Register A1 Update in Up/Down Counter Mode**

### 34.6.1.1.13 Output Pulse Width and Frequency Modulation (OPWFM) Mode

In this mode, duty cycle of output signal is the value defined in register A1 plus one and the period is the value defined in register B1 plus one. **MODE[6]** bit controls the transfer from register B2 to B1, which can be done either immediately (**MODE[6]** cleared, **MODE[0:6]=00110b0**), providing the fastest change in the duty cycle, or at every match of register A1 (**MODE[6]** set, **MODE[0:6]=00110b1**).

When OPWFM mode is entered, coming out from GPIO mode, the output flip-flop is set to the complement of the **EDPOL** bit in the **EMIOSC[n]** register.

The internal counter is automatically selected as a time base, therefore the BSL[0:1] bits in register EMIOSC[n] has no meaning. When a match on comparator A occurs, the output flip-flop is set to the value of the EDPOL bit. When a match occurs on comparator B, the output flip-flop is set to the complement of the EDPOL bit and the internal counter is cleared.

A FLAG can be generated at match B, when MODE[5] is cleared, or in both matches, when MODE[5] is set.

At any time, the FORCMA and FORCMB bits allow the software to force the output flip-flop to the level corresponding to a match on A or B respectively. Also, FORCMB clears the internal counter. Note that the FLAG bit is not set by the FORCMA or FORCMB operations.

If subsequent comparisons occur on comparators A and B, the PWFM pulses continue to be output, regardless of the state of the FLAG bit.

In order to achieve 100% duty cycle, both registers A1 and B1 must be set to the same value. When a simultaneous match occurs on comparators A and B, the output flip-flop is set to the value of EDPOL bit. 0% duty cycle is possible by writing 0x0 to register A. When a match occurs, the output flip-flop is set at every period to the complement of EDPOL bit. The transfer from register B2 to B1 is still controlled by MODE[6] bit.

### Note

Writing 0x0 to A1 and B1 produces a duty cycle of 0%.

Figure 34-141 shows the Unified Channel running in OPWFM mode with immediate register update and Figure 34-142 shows the Unified Channel running in OPWFM mode with next period update.

**Figure 34-141. OPWFM with immediate update (MODE[6] bit is 0b)**

**Figure 34-142. OPWFM with next period update (MODE[6] bit is 1b)**

#### 34.6.1.1.14 Output Pulse Width and Frequency Modulation Buffered (OPWFMB) Mode

This mode (MODE[0:6]=10110b0) provides waveforms with variable duty cycle and frequency. The internal channel counter is automatically selected as the time base when this mode is selected. Register A1 indicates the duty cycle and B1 register the frequency. Both registers A1 and B1 are double buffered to allow smooth signal generation when changing the registers values.. 0% and 100% duty cycles are supported.

At OPWFMB mode entry, the output flip-flop is set to the value of the EDPOL bit in the EMIOSC[n] register.

In order to provide smooth and consistent channel operation this mode differs substantially from the OPWFM mode. The main differences reside in the A1 and B1 registers update, on the delay from the A1 match to the output pin transition and on the range of the internal counter values which starts from 0x1 up to register B1 value.

When entering OPWFMB mode coming out of GPIO mode, the internal counter value is not within that range then the B match will not occur causing the channel internal counter to wrap at the maximum counter value which is 0xff\_fff for a 24-bit counter. After the counter wrap occurs it returns to 0x1 and resume normal OPWFMB mode operation. Thus in order to avoid the counter wrap condition make sure its value is within the 0x1 to B1 register value range when the OPWFMB mode is entered.

When a match on comparator A occurs the output register is set to the value of EDPOL. When a match on comparator B occurs the output register is set to the complement of EDPOL. B1 match also causes the internal counter to transition to 0x1, thus restarting the counter cycle.

Only values greater than 0x1 are allowed to be written to register B1. Loading values other than those leads to unpredictable results.

Figure 34-143 describes the operation of the OPWFMB mode regarding output pin transitions and A1/B1 registers match events. Note that the output pin transition occurs when the A1 or B1 match signal is deasserted which is indicated by the A1 match negedge detection signal. If register A1 is set to 0x4 the output pin transitions 4 counter periods after the cycle had started, plus one system clock cycle. Note that in the example shown in Figure 34-143 the internal counter prescaler has a ratio of two.

**Figure 34-143. OPWFMB A1 and B1 match to Output Register Delay**

Figure 34-144 describes the generated output signal if A1 is set to 0x0. Since the counter does not reach zero in this mode, the channel internal logic infers a match as if A1=0x1 with the difference that in this case, the posedge of the match signal is used to trigger the output pin transition instead of the negedge used when A1=0x1. Note that A1 posedge match signal from cycle  $n+1$  occurs at the same time as B1 negedge match signal from cycle  $n$ . This allows to use the A1 posedge match to mask the B1 negedge match when they occur at the same time. The result is that no transition occurs on the output flip-flop and a 0% duty cycle is generated.

**Figure 34-144. OPWFMB Mode with A1 = 0 (0% duty cycle)**

Figure 34-145 describes the timing for the A1 and B1 registers load. The A1 and B1 load use the same signal which is generated at the last system clock period of a counter cycle. Thus, A1 and B1 are updated respectively with A2 and B2 values at the same time that the counter (EMIOSCNT[n]) is loaded with 0x1. This event is defined as the cycle boundary. The load signal pulse has the duration of one system clock period. If A2 and B2 are written within cycle **n** their values are available at A1 and B1, respectively, at the first clock of cycle **n+1** and the new values are used for matches at cycle **n+1**. The update disable bits OU[n] of EMIOSOUDIS register can be used to control the update of these registers, thus allowing to delay the A1 and B1 registers update for synchronization purposes.

In Figure 34-145, it is assumed that both the channel and global prescalers are set to 0x1 (each divide ratio is two), meaning that the channel internal counter transitions at every four system clock cycles. FLAGS can be generated only on B1 matches when MODE[5] is cleared, or on both A1 and B1 matches when MODE[5] is set. Since B1 flag occurs at the cycle boundary, this flag can be used to indicate that A2 or B2 data written on cycle **n** were loaded to A1 or B1, respectively, thus generating matches in cycle **n+1**. Note that the FLAG has a synchronous operation, meaning that it is asserted one system clock cycle after the FLAG set event.

**Figure 34-145. OPWFMB A1 and B1 Registers Update and Flags (MODE6] bit is 0b)**

Figure 34-146 describes the operation of the Output Disable feature in OPWFMB mode. Differently from the OPWFM mode, the output disable forces the channel output flip-flop to EDPOL bit value. This functionality targets applications that use active high signals and a high to low transition at A1 match. In this case EDPOL should be set to 0. Note that both the channel and global prescalers are set to 0x0 (each divide ratio is one), meaning that the channel internal counter transitions at every system clock cycle.

**Figure 34-146. OPWFMB Mode with Active Output Disable (MODE[6] bit is 1b)**

Note that the output disable has a synchronous operation, meaning that the assertion of the Output Disable input pin causes the channel output flip-flop to transition to EDPOL at the next system clock cycle. If the Output Disable input is deasserted the output pin transition at the following A1 or B1 match.

In [Figure 34-146](#), it is assumed that the Output Disable input is enabled and selected for the Channel. Please, refer to UC Control Register (EMIOSCn) for a detailed description about the ODIS and ODISSL bits, respectively enable and selection of the Output Disable inputs.

The FORCMA and FORCMB bits allow the software to force the output flip-flop to the level corresponding to a match on comparators A or B respectively. Similarly to a B1 match FORCMB sets the internal counter to 0x1. The FLAG bit is not set by the FORCMA or FORCMB bits being asserted.

[Figure 34-147](#) describes the generation of 100% and 0% duty cycle signals. It is assumed EDPOL = 0 and the resultant prescaler value is 1. Initially, A1=0x8 and B1=0x8. In this case, B1 match has precedence over A1 match, thus the output flip-flop is set to the complement of EDPOL bit. This cycle corresponds to a 100% duty cycle signal. The same output signal can be generated for any A1 value greater or equal to B1.

**Figure 34-147. OPWFMB Mode from 100% to 0% Duty Cycle**

A 0% duty cycle signal is generated if A1=0x0 as shown in [Figure 34-147](#) cycle 9. In this case B1=0x8 match from cycle 8 occurs at the same time as the A1=0x0 match from cycle 9. Please, refer to [Figure 34-144](#) for a description of the A1 and B1 match generation. In this case A1 match has precedence over B1 match and the output signal transitions to EDPOL.

#### 34.6.1.1.15 Center Aligned Output Pulse Width Modulation with Dead Time Insertion (OPWMC) Mode

This operation mode generates a center aligned PWM with dead time insertion in the leading (MODE[0:6]=00111b1) or trailing edge (MODE[0:6]=00111b0).

The selected counter bus must be running an up/down time base, as shown in the 'Modulus Counter up/down mode example' figure. BSL[0:1] bits select the time base. Register A1 contains the ideal duty cycle for the PWM signal and is compared with the selected time base. Register B1 contains the dead time value and is compared with the internal counter. For a leading edge dead time insertion, the output PWM duty cycle is equal to the difference between register A1 and register B1, and for a trailing edge dead time insertion, the output PWM duty cycle is equal to the sum of register A1 and register B1. Mode[6] bit selects between trailing and leading dead time insertion, respectively.

#### Note

The internal counter may be running in the internal prescaler ratio, while the selected time base may be running in a different prescaler ratio. The output signal may produce an unexpected output if the dead time interval is greater than the duty cycle of the PWM signal.

When OPWMC mode is entered, coming out from GPIO mode, the output flip-flop is set to the complement of the EDPOL bit in the EMIOSC[n] register.

When operating with leading edge dead time insertion, the first match between A1 and the selected time base clears the internal counter and switches the selected time base to the internal counter. When a match occurs between register B1 and the selected time base, the output flip-flop is set to the value of the EDPOL bit and the time base is switched to the selected counter bus. In the next match between register A1 and the selected time base, the output flip-flop is set to the complement of the EDPOL bit. This sequence repeats continuously.

When operating with trailing edge dead time insertion, the first match between A1 and the selected time base sets the output flip-flop to the value of the EDPOL bit. In the next match between register A1 and the selected time base, the internal counter is cleared and the selected time base is switched to the internal counter. When a match occurs between register B1 and the selected time base, the output flip-flop is set to the complement of the EDPOL bit and the time base is switched to the selected counter bus. This sequence repeats continuously.

FLAG can be generated in the trailing edge of the output PWM signal when MODE[5] is cleared, or in both edges, when MODE[5] is set.

At any time, the FORCMA or FORCMB bits are equivalent to a successful comparison on comparator A or B with the exception that the FLAG bit is not set.

### Note

When in freeze state, the FORCMA or FORCMB bits only allow the software to force the output flip-flop to the level corresponding of a match on A or B respectively.

If subsequent matches occur on comparators A and B, the PWM pulses continue to be generated, regardless of the state of the FLAG bit.

In order to achieve a duty cycle of 100%, both registers A1 and B1 must be set to the same value. When a simultaneous match occurs between the selected time base and registers A1 and B1, the output flip-flop is set to the value of EDPOL bit and the selected time base switches to the selected counter bus, allowing a new cycle to begin at any time, as previously described. 0% duty cycle is possible by writing 0x0 to register A. When a match occurs, the output flip-flop is set to the complement of EDPOL bit and the selected time base switches to the selected counter bus, allowing a new cycle to begin at any time, as previously described. In both cases, FLAG is generated regardless of MODE[6] bit.

### Note

If A1 and B1 are set to the 0x0, a 0% duty cycle waveform is produced.

Figure 34-148 and Figure 34-149 show the Unified Channel running in OPWMC with leading and trailing dead time, respectively.

## Functional Description

**Figure 34-148. OPWMC with leading dead time insertion (MODE [6] bit is 1b)**

**Figure 34-149. OPWMC with trailing dead time insertion (MODE [6] bit is 0b)**

### 34.6.1.1.16 Output Pulse Width Modulation (OPWM) Mode

Registers A1 and B1 define the leading and trailing edges of the PWM output pulse, respectively. MODE[6] bit controls the transfer from register B2 to B1, which can be done either immediately (MODE[6] cleared, MODE[0:6]=01000b0), providing the fastest change in the duty cycle, or at every match of register A1 (MODE[6] set, MODE[0:6]=01000b1).

The value loaded in register A1 is compared with the value on the selected time base. When a match on comparator A occurs, the output flip-flop is set to the value of the EDPOL bit. When a match occurs on comparator B, the output flip-flop is set to the complement of the EDPOL bit.

A FLAG can be generated at match B, when MODE[5] is cleared, or in both matches, when MODE[5] is set.

At any time, the FORCMA and FORCMB bits allow the software to force the output flip-flop to the level corresponding to a match on A or B respectively. Note that FLAG bit is not set by the FORCMA and FORCMB operations.

If subsequent matches occur on comparators A and B, the PWM pulses continue to be generated, regardless of the state of the FLAG bit.

At OPWM mode entry the output flip-flop is set to the complement of the EDPOL bit in the EMIOSC[n] register.

In order to achieve 100% duty cycle, both registers A1 and B1 must be set to the same value. When a simultaneous match on comparators A and B occur, the output flip-flop is set at every period to the value of EDPOL bit. 0% duty cycle is possible by writing 0x0 to register A. When a match occurs, the output flip-flop is set at every period to the complement of EDPOL bit. The transfer from register B2 to B1 is still controlled by the MODE[6] bit.

#### Note

If A1 and B1 are set to the 0x0, a 0% duty cycle waveform is produced.

[Figure 34-150](#) and [Figure 34-151](#) show the Unified Channel running in OPWM with immediate update and next period update, respectively.

**Figure 34-150. PWM with immediate update (MODE[6] is 0b)**

**Figure 34-151. PWM with next period update (MODE[6] is 1b)**

### 34.6.1.1.17 Output Pulse Width Modulation Buffered (OPWMB) Mode

OPWMB mode (MODE[0:6]=11000b0) is used to generate pulses with programmable leading and trailing edge placement. An external counter driven in MCB Up mode must be selected from one of the counter buses. A1 register value defines the first edge and B1 the second edge. The output signal polarity is defined by the EDPOL bit. If EDPOL is zero, a negative edge occurs when A1 matches the selected counter bus and a positive edge occurs when B1 matches the selected counter bus.

The A1 and B1 registers are double buffered and updated from A2 and B2, respectively, at the cycle boundary. The load operation is similar to the OPWFMB mode. Please refer to [Figure 34-145](#) for more information about A1 and B1 registers update.

FLAG can be generated at B1 matches, when MODE[5] is cleared, or in both A1 and B1 matches, when MODE[5] is set. If subsequent matches occur on comparators A and B, the PWM pulses continue to be generated, regardless of the state of the FLAG bit.

FORCMA and FORCMB bits allow the software to force the output flip-flop to the level corresponding to a match on A1 or B1 respectively. The FLAG bit is not set by the FORCMA and FORCMB operations.

At OPWMB mode entry the output flip-flop is set to the value of the EDPOL bit in the EMIOSC[n] register.

Some rules applicable to the OPWMB mode are:

- B1 matches have precedence over A1 matches if they occur at the same time within the same counter cycle
- A1=0 match from cycle **n** has precedence over B1 match from cycle **n-1**
- A1 matches are masked out if they occur after B1 match within the same cycle
- Any value written to A2 or B2 on cycle **n** is loaded to A1 and B1 registers at the following cycle boundary (assuming OU[n] bit of EMIOSOUDIS register is not asserted). Thus the new values will be used for A1 and B1 matches in cycle **n+1**

The following figure describes the operation of the OPWMB mode regarding A1 and B1 matches and the transition of the channel output pin. In this example EDPOL is set to zero.

## Functional Description

**Figure 34-152. OPWMB Mode Matches and Flags**

Note that the output pin transitions are based on the negedges of the A1 and B1 match signals. The figure above shows in cycle *n+1* the value of A1 register being set to zero. In this case the match posedge is used instead of the negedge to transition the output flip-flop.

The figure below describes the channel operation for 0% duty cycle. Note that the A1 match posedge signal occurs at the same time as the B1=0x8 negedge signal. In this case A1 match has precedence over B1 match, causing the output pin to remain at EDPOL bit value, thus generating a 0% duty cycle signal.

**Figure 34-153. OPWMB Mode with 0% Duty Cycle**

Figure 34-154 describes the operation of the OPWMB mode with the Output Disable signal being asserted. The Output Disable forces a transition in the output pin to the EDPOL bit value. After deasserted, the output disable allows the output pin to transition at the following A1 or B1 match. Note that the Output Disable does not modify the Flag bit behavior. Note that there is one system clock delay between the assertion of the output disable signal and the transition of the output pin to EDPOL.

**Figure 34-154. OPWMB Mode with Active Output Disable (MODE[6] bit is 1b)**

Figure 34-155 shows a waveform changing from 100% to 0% duty cycle. EDPOL in this case is zero. In this example, B1 is programmed to the same value as the period of the external selected time base.

**Figure 34-155. OPWMB Mode from 100% to 0% Duty Cycle**

In Figure 34-155, if B1 is set to a value lower than 0x8, it is not possible to achieve 0% duty cycle by only changing A1 register value. Since B1 matches have precedence over A1 matches the output pin transitions to the opposite of EDPOL bit at B1 match. Note also that if B1 is set to 0x9, for instance, B1 match does not occur, thus a 0% duty cycle signal is generated.

### 34.6.1.2 Input Programmable Filter (IPF)

The IPF ensures that only valid input pin transitions are received by the Unified Channel edge detector. A block diagram of the IPF is shown in [Figure 34-156](#).

The IPF is a 5-bit programmable up counter that is incremented by the selected clock source, according to bits IF[0:3] in EMIOSC[n] register.

**Figure 34-156. Input Programmable Filter Submodule Diagram**

The input signal is synchronized by system clock. When a state change occurs in this signal, the 5-bit counter starts counting up. As long as the new state is stable on the pin, the counter remains incrementing. If a counter overflow occurs, the new pin value is validated. In this case, it is transmitted as a pulse edge to the edge detector. If the opposite edge appears on the pin before validation (overflow), the counter is reset. At the next pin transition, the counter starts counting again. Any pulse that is shorter than a full range of the masked counter is regarded as a glitch and it is not passed on to the edge detector. A timing diagram of the input filter is shown in [Figure 34-157](#).

**Figure 34-157. Input Programmable Filter Example (IF[0:3] is 0010b)**

The filter is not disabled during either freeze state or negated GTBE input

### 34.6.1.3 Clock Prescaler (CP)

The CP divides the GCP output signal to generate a clock enable for the internal counter of the Unified Channels. The GCP output signal is prescaled by the value defined in the UCPRE[0:1] field description in the EMIOSC[n] register. The prescaler is enabled by setting the UCPREN bit in the EMIOSC[n] and can be stopped at any time by clearing this bit, thereby stopping the internal counter in the Unified Channel.

In order to ensure safe working and avoid glitches the following steps must be performed whenever any update in the prescaling rate is desired:

1. Write 0 at both GPREN bit in EMIOSMCR register and UCPREN bit in EMIOSC[n] register, thus disabling prescalers;
2. Write the desired value for prescaling rate at UCPRE[0:1] bits in EMIOSC[n] register;
3. Enable channel prescaler by writing 1 at UCPREN bit in EMIOSC[n] register;
4. Enable global prescaler by writing 1 at GPREN bit in EMIOSMCR register.

The prescaler is not disabled during either freeze state or negated GTBE input.

### 34.6.1.4 Effect of Freeze on the Unified Channel

When in debug mode, FRZ bit in the EMIOSMCR register and the FREN bit in the EMIOSC[n] are both set, the internal counter and Unified Channel capture and compare functions are halted. The UC is frozen in its current state.

During freeze, all registers are accessible. When the Unified Channel is operating in an output mode, the force match functions remain available, allowing the software to force the output to the desired level.

Note that for input modes, any input events that may occur while the channel is frozen are ignored.

When exiting debug mode or freeze enable bit is cleared (FRZ in the EMIOSMCR or FREN in the EMIOSC[n] register) the channel actions resume, but may be inconsistent until channel enters GPIO mode again.

## 34.6.2 IP Bus Interface Unit (BIU)

The BIU provides the interface between the Internal Interface Bus (IIB) and the Peripheral Bus, allowing communication among all submodules and this IP interface.

The BIU allows 8, 16 and 32 bits access. They are performed over a 32-bit data bus in a single cycle clock.

### 34.6.2.1 Effect of Freeze on the BIU

When the FRZ bit in the EMIOSMCR register is set and the module is in debug mode, the operation of BIU is not affected.

### 34.6.3 STAC Bus Client submodule

The STAC bus client provides one external time base, imported from the STAC bus, to the Unified Channels. [Figure 34-158](#) provides a block diagram for the module.

**Figure 34-158. Block diagram**

Bits SRV[0:3] in register EMIOSMCR selects the desired time slot of the STAC bus to be output. [Figure 34-159](#) shows a timing diagram for the REDC.

NOTES: 1. Maximum of 16 Time Slots (TS[n])  
2. In this case, SRV bits were set to capture TS[01]

**Figure 34-159. Timing diagram for the STAC bus and STAC output**

Every time the selected time slot change, the STAC output is updated.

See the chip-specific eMIOS information for the STAC server IDs.

### 34.6.3.1 Effect of Freeze on the STAC bus

When the FRZ bit in the EMIOS\_MCR register is set and the module is in debug mode, the operation of REDC submodule is not affected, i.e., there is no freeze function in this submodule.

### 34.6.4 Global Clock Prescaler Submodule (GCP)

The GCP divides the system clock to generate a clock for the CPs of the channels. The main clock signal is prescaled by the value defined in the Global Prescaler clock divider table within the eMIOS Module Configuration Register (EMIOSMCR) description according to the GPRE[0:7] bits in EMIOSMCR register. The global prescaler is enabled by setting the GPREN bit in the EMIOSMCR register and can be stopped at any time by clearing this bit, thereby stopping the internal counters in all the channels.

In order to ensure safe working and avoid glitches the following steps must be performed whenever any update in the prescaling rate is desired:

1. Write 0 at GPREN bit in EMIOSMCR register, thus disabling global prescaler;
2. Write the desired value for prescaling rate at GPRE[0:7] bits in EMIOSMCR register;
3. Enable global prescaler by writing 1 at GPREN bit in EMIOSMCR register.

The prescaler is not disabled during either freeze state or negated GTBE input.

#### 34.6.4.1 Effect of Freeze on the GCP

When the FRZ bit in the EMIOSMCR register is set and the module is in debug mode, the operation of GCP submodule is not affected, i.e., there is no freeze function in this submodule.

## 34.7 Initialization/Application Information

On resetting the eMIOS, the Unified Channels enter GPIO input mode.

### 34.7.1 Considerations

Before changing an operating mode, the UC must be programmed to GPIO mode and EMIOSA[n] and EMIOSB[n] registers must be updated with the correct values for the next operating mode. Then the EMIOSC[n] register can be written with the new operating mode. If a UC is changed from one mode to another without performing this procedure, the first operation cycle of the selected time base can be random, i.e., matches

can occur in random time if the contents of EMIOSA[n] or EMIOSB[n] were not updated with the correct value before the time base matches the previous contents of EMIOSA[n] or EMIOSB[n].

When interrupts are enabled, the software must clear the FLAG bits before exiting the interrupt service routine.

## 34.7.2 Application Information

Correlated output signals can be generated by all output operation modes. Bits OU[n] of eMIOS\_OUDIS register can be used to control the update of these output signals.

In order to guarantee that the internal counters of correlated channels are incremented in the same clock cycle, the internal prescalers must be set up before enabling the global prescaler. If the internal prescalers are set after enabling the global prescaler, the internal counters may increment in the same ratio, but at a different clock cycle.

It is recommended to drive Output Disable Input signals with the emios\_flag\_out signals of some UCs running in SAIC mode. When an output disable condition happens, the software interrupt routine must service the output channels before servicing the channels running SAIC. This procedure avoid glitches in the output pins.

### 34.7.2.1 Time Base Generation

For MC and OPWFM with internal clock source operation modes, the internal counter rate can be modified by configuring the clock prescaler ratio. [Figure 34-160](#) shows an example of a time base with prescaler ratio equal to one.

#### Note

MCB and OPWFMB modes have a different behavior.

PRE SCALED CLOCK RATIO = 1 (bypassed)

**Figure 34-160. Time base period when running in the fastest prescaler ratio**

If the prescaler ratio is greater than one or external clock is selected, the counter may behave in one of four different ways depending on the channel mode:

- If MC mode and Clear on Match Start and External Clock source are selected the internal counter behaves as described in [Figure 34-161](#).
- If MC mode and Clear on Match Start and Internal Clock source are selected the internal counter behaves as described in [Figure 34-162](#).
- If MC mode and Clear on Match End are selected the internal counter behaves as described in [Figure 34-163](#).
- If OPWFM mode is selected the internal counter behaves as described in [Figure 34-162](#). The internal counter clears at the start of the match signal, skips the next prescaled clock edge and then increments in the subsequent prescaled clock edge.

## Note

MCB and OPWFMB modes have a different behavior.

**Figure 34-161. Time base generation with external clock and clear on match start**

PRESCALED CLOCK RATIO = 3

Note 1: When a match occurs, the first clock cycle is used to clear the internal counter, and only after a second edge of pre scaled clock the counter will start counting.

**Figure 34-162. Time base generation with internal clock and clear on match start**

Note 1: The match occurs only when the input event/prescaler clock enable is active. Then, the internal counter is immediately cleared.

**Figure 34-163. Time base generation with clear on match end**

### 34.7.2.2 Coherent Accesses

Reading the EMIOSA[n] register again in the same period of the last read of EMIOSB[n] register may lead to incoherent results. This will occur if the last read of EMIOSB[n] register occurred after a disabled B2 to B1 transfer.

### 34.7.2.3 Channel/Modes Initialization

The following basic steps summarize basic output mode startup, assuming the channels are initially in GPIO mode:

1. *[global]* Disable Global Prescaler.
2. *[timebase channel]* Disable Channel Prescaler.

3. [*timebase channel*] Write initial value at internal counter.
4. [*timebase channel*] Set A/B register.
5. [*timebase channel*] Set channel to MC(B) Up mode.
6. [*timebase channel*] Set prescaler ratio.
7. [*timebase channel*] Enable Channel Prescaler.
8. [*output channel*] Disable Channel Prescaler.
9. [*output channel*] Set A/B register.
10. [*output channel*] Select timebase input through BSL[1:0] bits.
11. [*output channel*] Enter output mode.
12. [*output channel*] Set prescaler ratio (same ratio as timebase channel).
13. [*output channel*] Enable Channel Prescaler.
14. [*global*] Enable Global Prescaler.
15. [*global*] Enable Global Time Base.

The timebase channel and the output channel may be the same for some applications such as in OPWFM(B) mode or whenever the output channel is intended to run the timebase itself.

At any time the flags can be configured.

# Chapter 35

## Enhanced Time Processing Unit (eTPU)

### 35.1 Chip-specific eTPU information

This chip contains three eTPU modules with the following configuration:

- 32 channels per eTPU module
- 36 KB code RAM total
- 9 KB parameter RAM total
- ETPU\_A and ETPU\_B share the same program and data (parameter RAM) space in a dual-engine configuration
  - Support for up to 200 MHz clock rate (provides 100 MHz instruction execution rate)
  - ECC support on parameter RAM and program space
  - Sizes of shared eTPU\_A and eTPU\_B memories:
    - SCM instruction memory address space: 24 KB code RAM
    - SDM data memory address space: 6 KB parameter RAM
  - No shared subsystem support and therefore no Shared Subsystem Integration registers (SSIRs)
- ETPU\_C has private program and parameter RAM space in a single-engine configuration
  - Support for up to 200 MHz clock rate (provides 100 MHz instruction execution rate)
  - ECC support on parameter RAM and program space
  - Sizes of eTPU\_C memories:
    - SCM instruction memory address space: 12 KB code RAM
    - SDM data memory address space: 3 KB parameter RAM

See also this information:

- [eMIOS global time base synchronization with eTPU](#)
- [DSPI connections with SIU, eTPU, and eMIOS modules](#)
- [eMIOS and eTPU ODIS connections](#)

### 35.1.1 eTPU register field reset values

The following table lists chip-specific reset values for register fields of the eTPU instances.

**Table 35-1. Chip-specific eTPU register field reset values**

| eTPU instance | Register field                 | Reset value | Notes                                                               |
|---------------|--------------------------------|-------------|---------------------------------------------------------------------|
| eTPU_A/B      | eTPU_SCR_MCR[SCMSIZE]          | 01011b      | The reset value of eTPU_SCR_MCR is 000B_0000h.                      |
| eTPU_A/B      | eTPU_TBR_STAC_ENG1[SERVER_ID1] | 0000b       | This is consistent with eTPU_A TCR1 in <a href="#">Table 35-2</a> . |
| eTPU_A/B      | eTPU_TBR_STAC_ENG1[SERVER_ID2] | 0010b       | This is consistent with eTPU_A TCR2 in <a href="#">Table 35-2</a> . |
| eTPU_A/B      | eTPU_TBR_STAC_ENG2[SERVER_ID1] | 0001b       | This is consistent with eTPU_B TCR1 in <a href="#">Table 35-2</a> . |
| eTPU_A/B      | eTPU_TBR_STAC_ENG2[SERVER_ID2] | 0011b       | This is consistent with eTPU_B TCR2 in <a href="#">Table 35-2</a> . |
| eTPU_C        | eTPU_SCR_MCR[SCMSIZE]          | 00101b      | The reset value of eTPU_SCR_MCR is 0005_0000h.                      |
| eTPU_C        | eTPU_TBR_STAC_ENG1[SERVER_ID1] | 0100b       | This is consistent with eTPU_C TCR1 in <a href="#">Table 35-2</a> . |
| eTPU_C        | eTPU_TBR_STAC_ENG1[SERVER_ID2] | 0101b       | This is consistent with eTPU_C TCR2 in <a href="#">Table 35-2</a> . |
| eTPU_C        | eTPU_TBR_STAC_ENG2[SERVER_ID1] | —           | eTPU_C does not have engine 2.                                      |
| eTPU_C        | eTPU_TBR_STAC_ENG2[SERVER_ID2] | —           | eTPU_C does not have engine 2.                                      |

### 35.1.2 Access to eTPU registers in chip-level Stop mode

On this chip, if you attempt to access eTPU registers when the chip is in Stop mode (as defined in [Modes of operation](#)), you will receive a bus error.

#### NOTE

This Stop mode corresponds to the chip-level Stop mode. It is different from the eTPU Module Disable mode, also defined in [Modes of operation](#).

### 35.1.3 STAC server IDs

On this chip, an eTPU module can export the TCR1 and TCR2 timebases on the STAC bus to an eMIOS or eQADC module. See [STAC interface](#) for more information.

An eTPU module is able to export a timebase to an eMIOS or eQADC module when the eTPU timebase period is equal to or greater than 6 times the eTPU clock frequency, regardless of whether the clock ratio between the eTPU and eMIOS or eQADC is 1:1 or 2:1.

STAC server IDs are defined in the following table.

No more than 4 STAC servers must be enabled at any time.

**Table 35-2. STAC server IDs**

| eTPU instance | Time base | Server ID |
|---------------|-----------|-----------|
| eTPU_A        | TCR1      | 0         |
| eTPU_A        | TCR2      | 2         |
| eTPU_B        | TCR1      | 1         |
| eTPU_B        | TCR2      | 3         |
| eTPU_C        | TCR1      | 4         |
| eTPU_C        | TCR2      | 5         |

### 35.1.4 eTPU inputs with Glitch Filters

See [IGF interaction with other modules](#) for connections between eTPU and Input Glitch Filters (IGFs).

### 35.1.5 eMIOS and eTPU signal passthrough from pins via IGFs

On this chip, the IGF modules mediate between some pins and the eMIOS and eTPU modules. After system reset, the IGF modules are in Configuration mode by default. This mode disables IGF output and prevents the signals from the pins from reaching the eMIOS and eTPU modules.

The signals affected by this situation appear in [IGF interaction with other modules](#).

To route an affected signal directly to an eMIOS or eTPU instance, program the applicable channel of the applicable IGF instance:

1. Ensure that IGF\_MCRn[MDIS] is 0 and that the IGF channel is disabled: IGF\_MCRn[FGEN] is 0.
2. Configure the rising and falling edges for bypass:
  - Rising edge: Write 00b to IGF\_MCRn[RFM].
  - Falling edge: Write 00b to IGF\_MCRn[FFM].
3. Enable the IGF channel: Write 1 to IGF\_MCRn[FGEN].

At the end of this sequence, the programmed filter enters Normal mode and passes through the affected signal.

### 35.1.6 eTPU output disable channel groups

The output disable channel groups are defined in the following table. See [Table 34-2](#) for additional information.

**Table 35-3. Output disable channel groups**

| Output disable signal | eTPU_A channels | eTPU_B channels | eTPU_C channels |
|-----------------------|-----------------|-----------------|-----------------|
| ODIS_1(0)             | 0 to 7          | –               | 0 to 7          |
| ODIS_1(1)             | 8 to 15         | –               | 8 to 15         |
| ODIS_1(2)             | 16 to 23        | –               | 16 to 23        |
| ODIS_1(3)             | 24 to 31        | –               | 24 to 31        |
| ODIS_2(0)             | –               | 0 to 7          | –               |
| ODIS_2(1)             | –               | 8 to 15         | –               |
| ODIS_2(2)             | –               | 16 to 23        | –               |
| ODIS_2(3)             | –               | 24 to 31        | –               |

### 35.1.7 Control of the eTPU Output Buffer Enable signal

On this chip, the eTPU Output Buffer Enable signal is controlled by the Pad Configuration Registers (PCRs) in the SIU. See [Table 8-3](#) and [Pad Configuration Register \(SIU\\_PCR<sub>n</sub>\)](#).

## 35.2 Device-specific Information

- Single (32 channels) or Dual (64 channels, dual core) Engine
- SCM size, error detection, error correction
- SDM size, error detection, error correction
- Nexus class 3 support
- GTBE is a logical OR with other modules (eMIOS, other eTPU)
- channel output buffers are controlled through the SIU, and cannot be controlled with microcode

- channels used to trigger the eQADC
- channels used to enable the Reaction Module modulation
- channels with DMA request
- TRC1, TRC2 STAC server IDs

## 35.3 Introduction

eTPU is an intelligent, semi-autonomous co-processor designed for timing control. Operating in parallel with the Host CPU, the eTPU processes instructions and real-time input events, performs output waveform generation, and accesses shared data without Host intervention. Consequently, for each timer event, the Host CPU setup and service times are minimized or eliminated.

High-level assembler, compiler and documentation allows customers to develop their own functions on the eTPU.

eTPU architecture aims at high resolution timing capabilities. From a system perspective, high resolution timing is limited by Host CPU overhead required for servicing timing tasks such as period measurement, pulse measurement, pulse width modulated waveform generation, etc. On the eTPU, high resolution timing is achieved by three main capabilities:

- Reduced latency: pin actions are immediate.
- Reduce or eliminate host interrupt service time.
- Double action channel capability reducing the channel request rate.

eTPU provides higher resolution than the Host CPU can achieve and creates no Host overhead for servicing timing tasks.

Latency is the interval from occurrence of an event to the start of event servicing. eTPU can service its own events without interrupting the Host. There are two types of timing events:

- Input pin transition.
- Selected Time Base match, i.e., a selected Time Base counter reached or exceeded a pre-programmed value.

Service time is the time spent servicing an event. In general, in microcontrollers the service time is constrained because the instruction set is not optimized for time function synthesis. The eTPU instruction set is optimized, so that time functions can be implemented with much fewer instructions than the Host CPU. Instructions execute faster, service time is reduced and program memory compacted.

Instructions executed by the eTPU are connected directly to the eTPU timing hardware and allow parallelism of hardware related actions.

### 35.3.1 Overview

The figure below shows a top-level eTPU block diagram. It displays a dual eTPU Engine configuration.

**Figure 35-1. eTPU Block Diagram**

**eTPU Engine** is responsible for processing input pin transitions and output pin waveform generation based on the **Time Bases**. Each eTPU Engine has its own microprocessor and dedicated hardware for processing signals on I/O pins and can also interface with external time bases through the STAC bus.

Both eTPU Engine CPUs, hereafter called **microengines**, fetch microinstructions from a **Shared Code Memory - SCM**.

**Shared Data Memory - SDM** - holds eTPU application parameters and work data. It is accessed by Host and both microengines.

**Bus Interface Unit - BIU** - allows Host to access eTPU registers, SCM and SDM.

Each I/O signal pair is associated with a dedicated **Channel**, which provides hardware for input signal processing and output signal generation, in relationship with selected Time Bases.

The eTPU, as a microprocessed subsystem, works much like a typical real-time system: it runs microengine code from instruction memory (SCM) to handle specific events, accessing data memory (SDM) for parameters, work data and application state info; events may originate from I/O Channels (due to pin transitions and/or time base matches), Host CPU requests or inter-channel requests; events that call for local eTPU processing activate the microengine by issuing a **Service Request**. The Service Request microcode may set an interrupt to the Host CPU. I/O channel events cannot directly interrupt the Host CPU.

Each Channel is associated with a **Function**, which defines its behavior: the Function is a software entity consisting, within the eTPU, of a set of microengine routines that attend to Service Requests. The Function routines are also responsible for Channel configuration. Function routines reside in SCM, which may contain several Functions. A Function may be assigned to several Channels, but a Channel can be associated with just one Function at a given moment. The association between Functions and Channels is defined by Host CPU, and is explained in detail in [Functions and threads](#).

eTPU hardware supplies resource sharing features that support concurrency:

- A hardware **Scheduler** dispatches the Service Request microengine routines based on a set of priorities defined by the Host CPU. Each Channel has its associated priority.
- A Service Request routine cannot be interrupted until it ends. This sequence of uninterrupted instruction execution is called a **Thread**.

- Channel-specific context (registers and flags) is automatically switched between the end of a Thread and the beginning of the next one.
- SDM arbitration, a dual-parameter coherency controller and semaphores can be used to ensure coherent access to eTPU data shared by both eTPU Engines and Host CPU.

### 35.3.1.1 eTPU Engine

Each eTPU Engine consists of all blocks that are duplicated in a dual eTPU configuration: two 24-bit time bases, 32 independent timer channels, a task scheduler, a microengine, and a Host interface. In addition, a 32-bit Shared Data Memory (SDM) is used for two eTPU Engines data storage and for passing information between the eTPU Engines and the Host CPU.

The following figure shows the block diagram for the eTPU Engine.

**Figure 35-2. eTPU Engine Block Diagram**

eTPU Engines 1 and 2 are sometimes called eTPU 1 and eTPU 2 for short throughout this chapter.

### 35.3.1.1.1 Time Bases

Two 24-bit counters TCR1 and TCR2 provide reference time bases for all match and input capture events. Prescalers for both time bases are controlled by the Host CPU through bit fields in the eTPU Engine configuration registers. The eTPU is able to export/import time to/from TCR1 or TCR2 in accordance to the STAC bus specification.

The clock for each of TCR1 and TCR2 clock can be independently derived from the eTPU clock or from an external input via the TCRCLK clock pin. In addition, the TCR2 timebase can be derived from special angle-clock hardware which enables implementing angle-based functions. This feature is added to support advanced angle based engine control applications.

For further details refer to [Time bases](#).

### 35.3.1.1.2 eTPU Timer Channels

Each eTPU Engine has 32 independent channels, each corresponding to an Input/Output signal pair. The channel time resolution is 24 bits, and are all identical.

Each channel consists of logic which supports two events and output controls. The event logic contains two 24-bit capture registers, two 24-bit match registers, greater-equal and equal-only comparators. Supporting two events enables many combinations of double action functions (for example the channel can handle two events with a single microcode service).

The channel configuration can be changed immediately by the microengine. Each channel can perform double capture, double match and other capture-match combinations. Channel modes available can do ordered or unordered match. Some modes are also provided that can block one match by the occurrence of the other. Service request can be generated on one or both of the match events.

Input signal can be separated from output signal in each channel. They can, optionally, be combined in a single I/O pin driver. An output buffer enable is controlled by the SIU (or SIUL). Digital filters are provided for the input signals, with distinct filtering modes available.

Each channel can use any time base or angle counter for either match or capture operation. For example, a match on TCR1 can capture the value of TCR2. The channels can request service from the microengine due to recognized pin transitions (input events) or timebase matches.

The eTPU channels also support the basic single-action operations found on TPU3 functionality with the exception that time resolution is 24-bits.

Channel configuration combinations:

- Single input capture, no match (TPU3 functionality)
- Single input capture with single match timeout (TPU3 functionality)
- Single input capture with double match timeout with several double match sub-modes
- Double input capture with single or double match timeout with several double match sub-modes
- Single output match (TPU3 functionality)

- Double output match with several double match sub-modes
- Input-dependent output generation

The double match functionality has various combinations for generation of service request and determining pin actions. For more details refer to [Enhanced Channels](#).

In addition to the predefined channel configurations above, the user can also program its own channel configuration, defining how input captures, matches and service-requests are related.

### 35.3.1.1.3 Host interface

The Host interface allows the Host CPU to control the operation of the eTPU. The Host CPU must initialize the eTPU by writing to the appropriate Host interface registers to assign a Function and priority to each channel. In addition, the Host writes to the Host Service Request and channel configuration registers to further define Function operation for each initialized channel. Refer to [Host interface](#) for a detailed description.

When the SCM is implemented by RAM, the Host must first initialize it with the proper microcode program prior to enabling any eTPU Function, and then enable eTPU access (which also disables Host access).

### 35.3.1.1.4 Shared Data Memory - SDM

The SDM works as data RAM which can be accessed by the Host CPU and up to two eTPU Engines. This memory is used for information transfer between the Host CPU and the eTPU, as data storage for the eTPU microcode program or for communication between the two eTPU Engines. SDM width is 32 bits, and is accessible by the Host as byte, 16-bit or 32-bit wide. eTPU can access it as full 32-bits, lower 24-bits or upper byte (8-bit).

The host can also access the SDM space mirrored in other area with Parameter Sign Extension (PSE). Parameter Sign Extension accesses differ from the usual host accesses to the original SDM area as follows:

- Writes are effective only to the lower 3 bytes of a word: the word's most significant byte is kept unaltered in SDM.
- Reads return the lower 3 bytes of a word sign-extended to 32 bits, i.e.: the most significant bit of the word's 2nd most significant byte is copied in all 8 bits of the most significant read byte.

Each eTPU channel can be associated with a variable number of parameters located in the SDM, according to its selected Function. In addition, the SDM can be fully shared between two eTPU Engines, enabling direct communication between them.

High flexibility of the SDM utilization is achieved as follows:

- Each channel has a programmable base address pointing to the address of its first parameter with two parameter granularity. This way the SDM can be partitioned according to the actual function needs.
- The microcode can access the first 128 parameters of the selected channel in channel relative access mode.
- Each Engine can access all the SDM address space in indirect addressing mode. Blocks of data are easily transferred using stack operation.
- Absolute addressing mode can access the first 256 parameters (TPU3 functionality), implementing a shared pool of parameters holding global variables.

In the Host address space each parameter occupies four bytes. eTPU usage of the upper byte is achieved by having a 32-bit P register which can access the upper byte, the lower 24 bits or all the 32 bits. The microcode can switch between access sizes at any time.

Each Function may require a different number of parameters. During the eTPU initialization the Host has to program channel base addresses, allocating proper parameters for each channel according to its selected Function.

#### **35.3.1.1.5 Shared Subsystem Area**

The Shared Subsystem (SSS) area is a memory map region used by both the host and the eTPU to access registers of the reaction channel, giving the user the option to control them by the host, the eTPU code, or a combination of both.

#### **35.3.1.1.6 Scheduler**

Out of reset, all channels are disabled. The Host CPU makes a channel active by assigning it one of three priorities: high, middle, or low. The Scheduler determines the order in which channels are serviced based on channel number and assigned priority. The priority mechanism, implemented in hardware, ensures that all requesting channels are serviced. For additional details refer to [Scheduler](#).

### 35.3.1.1.7 Microengine

eTPU microengine is a simple RISC implementation which performs each instruction in a microcycle of two eTPU clocks, while prefetching the next instruction through an instruction pipeline. Instruction execution time is constant unless it gets wait states from the SDM arbitration. Two eTPU Engines share code memory without having any performance degradation by interleaving their accesses (the Shared Code Memory has one-clock access time).

Instruction width is 32 bits. The microengine instruction set provides basic arithmetic and logic operations, flow control (jumps and subroutine calls), SDM access, and Channel configuration and control. The instruction formats are defined in such a way that allow particular combinations of two or three of these operations with unconflicting resources to be executed in parallel in the same microcycle.

Microengine has also an independent Multiply/Divide/MAC unit that performs these complex operations in parallel with other microengine instructions.

Channel functionality is tightly integrated to the instruction set through Channel Control operations and conditional Branch operations, which support jumps/calls on Channel-specific conditions. This allows quick and terse Channel configuration and control code, contributing to reduced service time.

Detailed description can be found in [Microengine](#).

### 35.3.1.1.8 Dual eTPU Engine System

A typical eTPU implementation includes two eTPU Engines sharing SDM and the same code in SCM.

The two eTPU Engines share the Bus Interface Unit (BIU) and the data memory (SDM) which enable Host-eTPU and eTPU Engine-Engine communication. The shared BIU includes coherency logic which supports dual parameter (8 bytes) coherency in transfers between Host and eTPU, using a temporary parameter area within the SDM. More details on this can be found on [Parameter sharing and coherency](#).

## 35.3.2 Features

The following sections show eTPU features and enhancements.

### 35.3.2.1 eTPU Feature Summary

The eTPU includes these distinctive features:

- up to 32 channels for each eTPU Engine, each channel is associated with an Input/Output signal pair.
  - enhanced input digital filters on the input pins for improved noise immunity. The eTPU digital filter can use 2 samples, 3 samples or work in continuous mode.
  - identical, orthogonal channels, except for channel 0: each channel can perform any time function. Each time function can be assigned to more than one channel at a given time, so each signal can have any functionality. Channel 0 has the same capabilities of the others, but can also work with special Angle Counter logic (see below).
  - Link Service Request allows activation of a Channel function by request of another channel, even between eTPU Engines.
  - Host Service Request allows activation of a Channel function by Host CPU request
  - each channel has an event mechanism which supports single and double action functionality in various combinations. It includes two 24-bit capture registers, two 24-bit match registers, 24-bit greater-equal and equal-only comparators.
- Two independent 24-bit time bases for channel synchronization:
  - first time base clocked by eTPU clock with programmable prescaler division from 1 to 512 (in steps of 2), or by output of second time base prescaler.
  - first time base can also be clocked by external signal with programmable prescaler division of 1 to 256.
  - second time base clocked by external signal with programmable prescaler division from 1 to 64.
  - second time base external clock source can be replaced by eTPU clock divided by 8.
  - both time bases can be exported or imported via Shared Time and Counter bus.
  - second time base counter can work as an Angle counter, enabling angle based applications to match angle instead of time.
  - second time base can also be used as a pulse accumulator gated by external signal.
- Event-Triggered RISC processor (microengine):
  - 3 stage pipeline implementation (fetch, decoding and execution), with separate instruction memory - SCM - and data memory - SDM (Harvard architecture)

- fixed-length instruction execution in one microcycle of two eTPU clocks
- interleaved SCM access in dual eTPU Engine avoids contention in time for instruction memory
- SCM address space of up to 16K positions (64 Kbytes) (see chip-specific eTPU information)
- SDM with interleaved access in dual eTPU Engine avoids contention for data memory
- SDM address space (both Engines) of up to 8 Kbytes (see chip-specific eTPU information)
- instruction set with embedded Channel support, including specialized Channel control subinstructions and conditional branching on Channel-specific flags.
- channel-oriented addressing: channel-bound address mode with Host configured Channel Base Address allows channel data isolation, independent of microengine application code.
- channel-bound data address space of up to 128 32-bit parameters (512 bytes)
- global parameter address mode allows access to common Channel data of up to 256 32-bit parameters (1024 bytes)
- support for indirect and stacked data access schemes.
- parallel execution of: data access, ALU, Channel control and flow control subinstructions in selected combinations.
- 32-bit microengine registers and 24-bit resolution ALU, with 1 microcycle addition and subtraction, absolute value, bitwise logical operations on 24-bit, 16-bit, or byte operands; single bit manipulation, shift and rotate operations, sign extension and conditional execution.
- additional 24-bit Multiply/MAC/Divide unit which supports all signed/unsigned Multiply/MAC combinations, and unsigned 24-bit Divide. The MAC/Divide unit works in parallel with the regular microcode commands.
- Resource sharing features support channel sharing of channel registers, memory and microengine time:
  - hardware Scheduler works as a "task management" unit, dispatching event service routines by predefined, Host-configured priority.

- automatic Channel context switch when a "task switch" occurs, i.e., one Function Thread ends and another begins to service a request from other Channel: Channel-specific registers, flags and parameter base address are automatically loaded for the next serviced channel.
- individual channel priority setting in 3 levels: high, middle and low.
- Scheduler priority scheme allows calculation of worst case latency for event servicing and ensures servicing all channels by preventing permanent blockage.
- SDM shared between Host CPU and both eTPU Engines, supporting communication either between Channels and Host or inter-channel.
- hardware implementation of 4 Semaphores supports resource sharing between both eTPU Engines.
- Hardware semaphores directly supported by the microengine instruction set.
- dual parameter coherency hardware support allows atomic (to host) access to 2 parameters by microengine(s) in back-to-back accesses.
- coherent dual-parameter controller allows atomic (to microengines) accesses to 2 parameters by the host.
- Development support features:
  - Nexus class 3 debug support (optional, associated with the eTPU-Nexus Block NDEDI).
  - Software breakpoints.
  - Debug interface supporting single-step execution, forced microinstruction execution, Hardware breakpoints and watchpoints on several conditions.
- Safety support features:
  - SCM (code memory) continuous signature-check built-in self test (MISC - Multiple Input Signature Calculator), runs concurrently with eTPU normal operation.
  - See [eTPU Plus Enhancements over eTPU](#) for additional safety features.

### 35.3.2.2 eTPU Enhancements over TPU3

- 32 orthogonal channels with enhanced functionality. Full support for double action with double match and double transition sub-mode combinations.

- Input and Output features separated in channel logic and microinstructions, allowing input and output signals to be processed separately or combined.
- Increased time resolution and execution unit to 24 bits.
- Increased linear code memory, shared by two eTPU Engines, configurable up to 16K positions (64 KB).
- Increased SDM address range (8 KB each Engine) and width (32 bits per parameter). The SDM can be dynamically allocated to support variable number of parameters for each channel. Each channel can have access to at least 256 parameters.
- The SDM is fully shared by two eTPU Engines (SDM), supporting direct inter-engine communication with the help of hardware semaphores.
- Enhanced arithmetic operations, including add/subtract with carry, absolute value, multiple shift and rotate, conditional execution with variable operand widths.
- Enhanced logic operations, including bitwise operations (and, or, xor) and bit manipulation, with conditional execution. Support for read-modify-write of any bit in the SDM.
- Hardware for Multiply/MAC/Divide, running in parallel to execution of other operations. The 24-bit divide result is available after 13 other unrelated instructions. Multiplication supports any data width of both operands (8, 16 or 24 bits), signed or unsigned. A 24x24 Multiply/MAC result is available after four other unrelated instructions. A 24x8 Multiply/MAC result is available after one other unrelated instruction.
- Supports export/import of time bases from other sources through the real time bus (STAC - Shared Time and Counter bus). This internal bus is used for sharing real time data between multiple peripherals.
- Contains angle clock hardware, supported by microcode, which can provide a 24-bit angle bus instead of time bus. This feature enables the eTPU to run angle based engine control applications.
- More interrupt types. Each eTPU channel can generate a data transfer request interrupt, in addition to regular interrupts, and one global exception interrupt. Data Transfer requests can be used either as interrupt sources or DMA requests. This feature takes advantage of DMA peripherals which off-load the Host. Interrupt Overflow status is also provided.
- Improved visibility to the Host (pin states, time bases, serviced channel).

- An edge case of priority inversion on TPU3 Scheduler was resolved.
- Supports channel link requests between eTPU Engines.

### 35.3.2.3 eTPU Plus Enhancements over eTPU

eTPU Plus features include the enhancements below in addition to all eTPU features

- TCR1, channel logic and digital filters (both channel and TCRCLK) now have an option to run at divisions of full eTPU clock speed, besides eTPU clock / 2 (see [T2/T4 channel timing](#)).
- Channels support unordered transitions: transition B can now be detected before transition A. Related to this enhancement, TDLA and TDLB can now be independently negated by microcode (see [Channel Mode Logic and Event Flags](#))
- Channel logic can now work on full eTPU clock, allowing faster response with slow clocks (see [T2/T4 channel timing](#)).
- Added a new User Programmable Channel Mode: the blocking, enabling, service request and capture characteristics of this channel mode can be programmed via microcode (see [General Channel registers](#)).
- Microinstructions now provide an option to issue Interrupt and Data Transfer requests selected by CHAN. They can also be requested simultaneously at the same instruction (see [Channel Interrupt and Data Transfer Requests](#)).
- Channel Flags 0 and 1 can now be tested for branching, besides selecting the entry point (see [Branch Operations](#)).
- Channel digital filters can be bypassed, and can be clocked by full eTPU clock (see [Bypass Mode](#)).

Backward compatibility is maintained so that all legacy object code (both Host and microcode) runs on eTPU Plus without modification.

### 35.3.2.4 eTPU2 enhancements over eTPU Plus

eTPU2 features include the enhancements below in addition to all eTPU Plus enhancements and eTPU features.

- Scheduler priority-passing mechanism can now be disabled (see [Priority passing disabling](#)).
- New Watchdog mechanism kills threads over a programmable timeout (see [Watchdog](#)).
- New counter allows microengine load information collection for performance analysis (see [Idle Counter](#)).
- Channels 1 and 2 (besides channel 0) can now be selected to control the EAC (see the TBCR\_ENG1 and TBCR\_ENG2 eTPU Time Base Configuration Registers).
- Timebase prescalers are now reset when the GTBE input is negated, guaranteeing synchronization with eMIOS in all cases (see [GTBE - Global Time Base Enable](#)).
- New MISC flag indicates when an SCM signature calculation round is completed. This allows measuring of the average MISC scan period in a real application situation (see the eTPU Module Configuration Register - MCR).
- New channel TCCEA flag allows continuous capture even after TDLA is set, making it fully compatible with TPU behavior (see [TCCEA - Transition Continuous Capture Enable](#)).
- New branch condition PRSS tells the pin state at the time when a channel (match or transition) service request occurred (see [Pin Control Registers](#)).
- MRLEA/B can now be negated independently by microcode (see [Disable Matches](#)).
- New Engine Relative address mode allows a function to access SDM address space common to one engine, but distinct between engines (see Engine Relative Addressing Mode under [SDM Addressing Modes](#)).
- Memory error support for Code (SCM) and Data (SDM) memories: error detection, correction, and hardware-assisted soft-error fixing (see [Memory error support](#)).
- Sharing of microengine and host accesses to subsystem modules (for instance, the Reaction Module), allowing their control by the eTPU, the host, or both (see [Shared Subsystems support](#)).

Backward compatibility is maintained so legacy object code (both Host and microcode) runs on eTPU2 without modification.

### 35.3.2.5 eTPU2 Plus enhancements over eTPU2

eTPU2 Plus features include the enhancements listed below in addition to all eTPU features, eTPU Plus enhancements and eTPU2 enhancements.

- New Latency Monitor allows latency measurements, either for individual channels or channels combined in a single priority (High, Medium or Low).
- Watchdog can now be configured to disable thread forced ending and channel blocking, allowing it to monitor thread lengths with no interference on the application.

- EAC Angle Tick Generator can now be clocked by the TCR2 prescaler output, as an alternative to the TCR1 clock.
- EAC now supports up to 7 missing teeth on hardware.

Backward compatibility is maintained so legacy object code (both Host and microcode) runs on eTPU2 Plus without modification.

### 35.3.3 Modes of operation

eTPU can be seen as capable of working in the following modes:

- **User Configuration Mode**

User has the ability to program the eTPU Cores with User Time Functions, having access to the Shared Code Memory (SCM).

- **User Mode**

User does not access the eTPU Shared Code Memory:

- Use of predefined eTPU Functions
- No need for eTPU Core programming ability

- **Debug Mode**

User debugs eTPU code, accessing special Trace/Debug features via Nexus interface:

- hardware breakpoint/watchpoint setting
- access to internal registers
- single-step execution
- forced instruction execution
- software breakpoint insertion and removal.

- **Module Disable Mode**

eTPU Engine clocks are stopped through a register write to the MDIS field in [eTPU Engine 1 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG1\)](#) and [eTPU Engine 2 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG2\)](#), saving power. Input sampling stops. eTPU Engines can be in Module Disable Mode independently. Module Disable Mode stops only the Engine clock, so that the Shared BIU, and Global

Channel registers can be accessed, and interrupts and DMAs can be cleared and enabled/disabled. An Engine only enters Module Disable Mode when any currently running thread is finished (see [Functions and threads](#)).

- **Stop Mode**

Stop Mode is entered when eTPU answers device stop request assertion with stop acknowledge. The definition of which clocks are stopped is made at the MCU level, which defines whether or not registers can be accessed, interrupts and DMA requests cleared.

These modes are loosely selected: there is no unique register field or signals to choose between them. Some features of one mode can be used with features of other mode(s). More on this subject can be found on [eTPU mode selection](#) below.

### Note

Throughout this chapter, an engine is said to be "stopped" if it is either in Module Disable mode or Stop mode.

### 35.3.3.1 eTPU mode selection

User and User Configuration are the production operating modes, and differ from each other only in access to SCM. User programmability is only possible with a RAM SCM.

On chips where the SCM is implemented as a RAM, it can either be accessed directly from IP-Bus for code loading, or for software breakpoint setting. On chips with a ROM SCM, an internal SCM Emulation RAM may be used, depending on the specific MCU implementation, to replace ROM SCM for test or debug purposes. SCM Emulation RAM is selected in a MCU-specific way. For more details, see [SCM Emulation](#).

Debug Mode is characterized by the use of the debug interface features. Specifically, Nexus blocks provide Nexus class 3 debug features. For more information on debug features, refer to [Development support features](#).

Module Disable Mode is entered by setting the MDIS field in [eTPU Engine 1 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG1\)](#) and [eTPU Engine 2 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG2\)](#). eTPU Engines can be individually stopped going into Module Disable Mode (there is one eTPU\_SCR\_ECR register for each Engine). Each engine can leave Module Disable Mode by writing MDIS=0 (which can only be done if VIS=0).

Stop Mode is activated by IP-Bus ( device stop request). In this case, the eTPU waits for both eTPU Engines to enter in stop mode, and then asserts the stop acknowledge line. eTPU leaves Stop Mode when device stop request is negated, but only if VIS=0. If device stop request is negated and VIS=1, eTPU will leave Stop Mode as soon as VIS=0.

### **Note**

An Engine can stay in Module Disable mode when it leaves Stop Mode if its bit MDIS=1, even if the other leaves it.

## **35.4 Detailed signal descriptions**

Detailed signal descriptions are presented in the following sections.

### **35.4.1 eTPU channel output signals**

Each channel output signal is associated with a channel. The microcode may affect the logic level of an output signal<sup>1</sup> by implementing one of two actions:

- Specify the logic level output to the signal when there is a match or a transition.
- Immediately force a logic level.

The output signal may also be forced to a logic level, independently of the output value from the channel logic, by one of the four (each Engine) output disable input signals (see [eTPU channel output disable signals](#)).

The output buffer enable signals are not used.

### **35.4.2 eTPU channel input signals**

Each channel input signal is associated with a channel. The microcode can directly control the effect of the transition edge. Each channel can be programmed to sense a transition when a rising and/or falling edge is detected. The channel logic can also process two transition events, and relate these events to each other and to other programmed timer events. The edge sensitivities of the two transition events are configured independently by microcode. For further information refer to [Enhanced Channels](#) and [Transition Detection and Pin Action Control](#).

---

1. Note that the minimum pulse width is one microcycle (two eTPU clocks), and slow pads may not be able to transfer it on time. For generation of very short pulses the eTPU pads have to be programmed by the system integration for fast operation mode with the voltage levels defined for fast pad operation in the MCU technology.

Each channel input signal has an associated synchronizer made of two flip-flops sampling the signal on every other eTPU clock<sup>2</sup>, followed by a digital filter. This digital filter can work in three sub-modes, whose purpose is to filter out noise pulses that have width less than a programmed value of eTPU clocks, preventing these transitions from being input to the transition detect logic. The synchronizer and digital filter are guaranteed to pass pulses that are greater than a programmed value. All channel input filters in one Engine work on the same mode and sampling clock. For more information on channel input filters, refer to [Enhanced Digital Filter - EDF](#). In one of the Angle Modes, the output of the digital filter of channel 0 is replaced by the output of TCRCLK signal digital filter (see [EAC - eTPU Angle Counter](#)).

### 35.4.3 Time Base Clock Signal — TCRCLK

TCRCLK is an input signal used to control the Time Bases TCR1 and TCR2. There is one independent TCRCLK input for each Engine. For pulse accumulator operations TCRCLK can be used as a gate for a counter based on the eTPU clock divided by eight. For Angle operations TCRCLK can be used to get the tooth transition indications in Angle Mode. Further details can be found on [Time bases](#) and [EAC - eTPU Angle Counter](#).

Like the channel input signals, the TCRCLK signal has an associated synchronizer followed by a digital filter. This digital filter can work in two sub-modes, whose purpose is to filter out noise pulses that have width less than a programmed value of eTPU clocks, preventing these transitions from being input to the transition detect logic. The synchronizer and digital filter are guaranteed to pass pulses that are greater than a programmed value. The clock and operation sub-mode of the TCRCLK filter is configured independently of the other channel input filters, through the TCRCF field in [eTPU Engine 1 Time Base Configuration Register \(eTPU\\_TBR\\_TBCR\\_ENG1\)](#) and [eTPU Engine 2 Time Base Configuration Register \(eTPU\\_TBR\\_TBCR\\_ENG2\)](#). For more information on filter sub-modes, see [TCRCLK digital filter](#). In one of the Angle Modes, the output of the digital filter of channel 0 is replaced with the output of TCRCLK signal digital filter (see [EAC - eTPU Angle Counter](#)).

### 35.4.4 eTPU channel output disable signals

Each of these 4 input signals are used to force the outputs of a group of 8 channels to an inactive level. When an ODIS input is active, all the channels in its group of 8 that have their fields ODIS=1 in [eTPU Channel n Configuration Register for Engine 1 \(eTPU\\_CCCR\\_CnCR\\_ENG1\)](#) and [eTPU Channel n Configuration Register for Engine 2](#)

2. Sampled on the T4 microcycle phase, see [Microcycle and I/O timing](#).

([eTPU\\_CCCR\\_CnCR\\_ENG2](#)) have their outputs forced to the opposite of the value specified in bit OPOL of the same register. Therefore, channels can be individually selected to be affected by the output disable signals, as well as their disabling forced polarity (see 'Pin State Input/Output Logic' figure in [Pin Control Registers](#)).

See the chip-specific eTPU information for details on the output channel disable group definition.

In a Dual-engine eTPU there are 8 output disable signals for the 64 channels.

## 35.5 Memory map/register definition

The guideline for the description of all bits and fields throughout the “Memory Map/ Register Definition” section is to provide only a brief explanation (without examples or method of use) of the features, since it will be used mainly as a reference for the reader that is studying the “Functional Description” section, where those features are explained in detail.

## 35.6 Memory map

The eTPU System simplified memory map is shown in [Table 35-4](#). Each of the register areas shown may have their own reserved address areas.

[Table 35-5](#) shows a detailed memory map. Offsets are relative to the eTPU Base address, which is MCU-dependent.

See the chip-specific eTPU information about accessing eTPU registers in chip-level Stop mode.

SCM unused area is decoded and returns a fixed opcode, determined by [eTPU SCM Off-range Data Register \(eTPU\\_SCR\\_SCMOFFDATAR\)](#).

**Table 35-4. High-level memory map**

| Offset      | Use                            |
|-------------|--------------------------------|
| 0x00 – 0x1F | System Configuration Registers |
| 0x20 – 0x2F | eTPU 1 Time Base Registers     |
| 0x30 – 0x3F | Reserved <sup>1</sup>          |
| 0x40 – 0x4F | eTPU 2 Time Base Registers     |
| 0x50 – 0x5F | Reserved <sup>1</sup>          |
| 0x60 – 0x6F | eTPU 1 Extra Engine Registers  |
| 0x70 – 0x7F | eTPU 2 Extra Engine Registers  |

*Table continues on the next page...*

**Table 35-4. High-level memory map (continued)**

| Offset                         | Use                                     |
|--------------------------------|-----------------------------------------|
| 0x80 – 0xFF                    | Latency Monitor Registers               |
| 0x100 – 0x13F                  | Memory Error Support Registers          |
| 0x140 – 0x1FF                  | Reserved <sup>1</sup>                   |
| 0x200 – 0x2FF                  | eTPU 1/2 Global Channel Registers       |
| 0x300 – 0x3FF                  | Reserved <sup>1</sup>                   |
| 0x400 – 0x7FF                  | eTPU 1 Channel Registers                |
| 0x800 – 0xBFF                  | eTPU 2 Channel Registers                |
| 0xC00 – 0xFFF                  | Shared Subsystems Integration Registers |
| 0x1000 – 0x3FFF                | Reserved <sup>1</sup>                   |
| 0x4000 – 0x7FFF                | SSS - Shared Subsystems area            |
| 0x8000 – 0xBFFF <sup>2</sup>   | SDM - Shared Data Memory                |
| 0xC000 – 0xFFFF <sup>2</sup>   | SDM PSE mirror <sup>3</sup>             |
| 0x10000 – 0x1FFFF <sup>2</sup> | SCM - Shared Code Memory <sup>4</sup>   |

1. Reserved addresses must not be used. Access to these memory positions complete with 0-wait-states, but the result is unspecified.
2. Actual sizes of SCM and SDM are MCU-dependent (see the chip-specific eTPU information).
3. Parameter Sign Extension access area, see [Parameter Access](#).
4. SCM access is available only when bit VIS=1 on register eTPU\_SCR\_MCR, under certain conditions (see [MCR](#)).

**Table 35-5. Detailed memory map**

1. This register is not implemented in some MCUs; see [SCMOFFDATAR](#).
2. These registers are not implemented in some MCUs; see [Memory error support](#).
3. The actual SDM size is MCU-dependent (see the chip-specific eTPU information). SDM is allocated from the starting value of the given range of offsets.
4. Parameter Sign Extension access area, see [Parameter Access](#).
5. The actual SCM size is MCU-dependent (see the chip-specific eTPU information). SCM is allocated from the starting value of the given range of offsets. When the size is not the maximum, the unused SCM address range returns the value of [SCMOFFDATAR](#).
6. SCM access is available only when eTPU\_SCR\_MCR[VIS]=1, under certain conditions (see [MCR](#)).

## 35.7 System Configuration memory map and registers

### 35.7.1 eTPU Module Configuration Register (eTPU\_SCR\_MCR)

This register is global to both eTPU engines, and resides in the shared BIU. It gathers global configuration and status in the eTPU system, including global exception. It is also used for configuring the SCM (shared code memory) operation and test.

Address: 0h base + 0h offset = 0h

| Bit   | 0   | 1      | 2     | 3     | 4    | 5    | 6    | 7    | 8      | 9 | 10 | 11      | 12 | 13 | 14 | 15 |
|-------|-----|--------|-------|-------|------|------|------|------|--------|---|----|---------|----|----|----|----|

| Field          | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
|----------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 20<br>SCMMISC  | <p>SCM MISC Complete flag.</p> <p>Flag SCMMISC indicates that MISC has completed the evaluation of the SCM signature since reset or since the last time it was cleared. SCMMISC is cleared by writing 1 to it, and is not cleared when MISC is disabled (SCMMISEN=0). SCMMISC asserts at the end of the SCM memory scan, either if the signature matches or not.</p> <p>0 MISC has not yet completed an SCM signature calculation and compare since the last time SCMMISC was cleared.</p> <p>1 MISC completed at least one SCM signature calculation and compare since the last time SCMMISC was cleared.</p>                                                                                                                                                                                                                                                    |
| 21<br>SCMMISF  | <p>SCM MISC Flag.</p> <p>The SCMMISF bit is set by the SCM MISC (Multiple Input Signature Calculator) logic to indicate that the calculated signature does not match the expected value, at the end of a MISC iteration. See <a href="#">SCM Test - Multiple Input Signature Calculator</a> for more details.</p> <p>This bit is cleared when Global Exception is cleared by writing 1 to GEC.</p> <p>0 Signature mismatch not detected.</p> <p>1 MISC has read entire SCM array and the expected signature in <a href="#">eTPU MISC Compare Register (eTPU_SCR_MISCCMPR)</a> does not match the value calculated.</p>                                                                                                                                                                                                                                            |
| 22<br>SCMMISEN | <p>SCM MISC Enable.</p> <p>The SCMMISEN bit is used for enabling/disabling the operation of the MISC logic. SCMMISEN is readable and writable at any time. The MISC logic will only operate when this bit is set to 1. When the bit is reset, the MISC address counter is set to the initial SCM address. When enabled, the MISC will continuously cycle through the SCM addresses, reading each and calculating a CRC. In order to save power, the MISC can be disabled by clearing the SCMMISEN bit. See <a href="#">SCM Test - Multiple Input Signature Calculator</a> for more details.</p> <p>SCMMISEN resets automatically when MISC logic detects an error, i.e., when SCMMISF transitions from 0 to 1, disabling the MISC operation.</p> <p>0 MISC operation disabled. The MISC logic is reset to its initial state.</p> <p>1 MISC operation enabled.</p> |
| 23<br>SCMERR   | <p>SCM Read Error.</p> <p>This flag indicates that an SCM non-correctable read error occurred on a host or microengine (including MISC) read, generating a Global Exception. This bit is cleared by writing 1 to GEC.</p> <p>0 No Global Exception pending because of SCM read error.</p> <p>1 Global Exception requested by SCM read error is pending.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| 24<br>Reserved | <p>This field is reserved.</p> <p>This read-only field is reserved and always has the value 0.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| 25<br>VIS      | <p>SCM Visibility Bit.</p> <p>VIS bit turns SCM visible to the IP-Bus and resets MISC state (but SCMMISEN keeps its value).</p> <p>This bit is write protected when any of the Engines is not halted or stopped.</p> <p>When VIS=1, the MDIS bits in the eTPU Memory Error Support registers are write protected.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |

## eTPU\_SCR\_CDCR field descriptions

| Field          | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|----------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0<br>STS       | <p>Start Bit.</p> <p>This bit is set by the host in order to start the data transfer between the parameter buffer pointed by PBBASE and the target addresses selected by the concatenation of fields CTBASE and PARM0/1. The host receives wait-states until the data transfer is complete, when this bit is reset by the coherency logic (see <a href="#">Coherent Dual-parameter Controller (CDC)</a>). Therefore, host always reads STS as 0.</p> <p>0 Write does not start a coherent transfer.<br/>1 Write starts a coherent transfer.</p> |
| 1–5<br>CTBASE  | <p>Channel Transfer Base.</p> <p>This field concatenates with fields PARM0 and PARM1 to determine the absolute word offset (from the SDM base) of the parameters to be transferred:</p> <p>Parameter 0 word address = {CTBASE, PARM0} + SDM base word address.<br/>Parameter 1 word address = {CTBASE, PARM1} + SDM base word address.</p>                                                                                                                                                                                                      |
| 6–15<br>PBBASE | <p>Parameter Buffer Base Address.</p> <p>This field points to the base address of the parameter buffer location, with granularity of 2 parameters (8 bytes). The host (byte) address of the first parameter in the buffer is PBBASE * 8 + SDM Base Byte Address. The microengine absolute (word) address of the first parameter in the buffer is PBBASE * 2.</p>                                                                                                                                                                                |
| 16<br>PWIDTH   | <p>Parameter Width Selection.</p> <p>This bit selects the width of the parameters to be transferred between the PB and the target address.</p> <p>0 Transfer 24-bit parameters. The upper byte remains unchanged in the destination address.<br/>1 Transfer 32-bit parameters. All 32 bits of the parameters are written in the destination address.</p>                                                                                                                                                                                        |
| 17–23<br>PARM0 | <p>Channel Parameter number 0.</p> <p>The PARM0 and PARM1 fields in concatenation with CTBASE determine the word address offset (from the SDM base) of the parameters that are destination or source (defined by WR) of the coherent transfer. The word SDM address offset of the parameters are {CTBASE, PARM0/1}.</p> <p><b>NOTE:</b> PARM0 and PARM1 allow non-contiguous parameters to be transferred coherently. The parameter pointed by {CTBASE, PARM0} is the first transferred.</p>                                                    |
| 24<br>WR       | <p>Read/Write selection.</p> <p>This bit selects the direction of the coherent data transfer.</p> <p>0 Read operation. Data transfer is from the selected SDM address to the PB.<br/>1 Write operation. Data transfer is from the PB to the selected SDM address.</p>                                                                                                                                                                                                                                                                           |
| 25–31<br>PARM1 | <p>Channel Parameter number 1.</p> <p>The PARM0 and PARM1 fields in concatenation with CTBASE determine the word address offset (from the SDM base) of the parameters that are destination or source (defined by WR) of the coherent transfer. The word SDM address offset of the parameters are {CTBASE, PARM0/1}.</p> <p><b>NOTE:</b> PARM0 and PARM1 allow non-contiguous parameters to be transferred coherently. The parameter pointed by {CTBASE, PARM0} is the first transferred.</p>                                                    |

### 35.7.3 eTPU MISC Compare Register (eTPU\_SCR\_MISCCMPR)

This register holds the 32-bit signature expected from the whole SCM array. This register must be written by the host with the 32-bit word to be compared against the calculated signature at the end of the MISC cycle. This register is global to both eTPU Engines. For more detail, see [SCM Test - Multiple Input Signature Calculator](#).

Address: 0h base + Ch offset = Ch

### 35.7.4 eTPU SCM Off-range Data Register (eTPU\_SCR\_SCMOFFDATAR)

This register holds the 32-bit value returned when SCM array is accessed at non-implemented addresses, either by the Host or by the microengine. This register can be written by the host with the 32-bit instruction to be executed by the microengine to recover from runaway code. This register is global to both eTPU Engines. For more detail see [SCM Off-range data](#).

Address: 0h base + 10h offset = 10h

|               | <p>This bit is self-negating when the thread ends.</p> <p><b>NOTE:</b> Only on rare occasions (e.g., during a long stall, see <a href="#">Microengine Stall</a>) FEND can be read as 1, because it negates as soon as the end begins execution.</p> <p>Writing FEND = 1 is ignored and FEND stays 0 when the microengine is in TST, halted, stopped, or idle (no thread executing).</p> <p>0 Normal operation.</p> <p>1 Ends any ongoing thread.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| 1<br>MDIS     | <p>Module Disable Bit.</p> <p>When MDIS is set, the Engine shuts down its internal clocks, going into Module Disable Mode. TCR1 and TCR2 cease to increment, and input sampling stops. The Engine asserts the stop flag (STF) bit to indicate that it has stopped. However, the BIU continues to run, and the Host can access all registers except for the channel registers (see channel registers starting with <a href="#">eTPU Channel n Configuration Register for Engine 1 (eTPU_CCCR_CnCR_ENG1)</a>)</p> <p><b>NOTE:</b> The Timebase registers can still be read with MDIS=1, but writes are ineffective and a Bus Error is issued. Global Channel Registers and SDM can be accessed normally.</p> <p>After MDIS is set, even before STF asserts, data read from the channel registers is not meaningful and writes are ineffective, issuing a Bus Error. When the MDIS bit is asserted while the microcode is executing, the eTPU will stop when the thread is complete.</p> <p>Stop completes on the next eTPU clock after the stop condition is valid.</p> <p><b>NOTE:</b> Once MDIS is switched from 1 to 0 or vice versa, it must not write a different value until STF changes accordingly.</p> <p>The MDIS bit is write-protected when VIS=1.</p> <p>See Register Reset Values in the chip-specific eTPU information.</p> <p>0 eTPU Engine runs.</p> <p>1 Commands Engine to stop its clocks.</p> |
| 2<br>Reserved | <p>Reserved.</p> <p>This field is reserved.</p> <p>This read-only field is reserved and always has the value 0.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| 3<br>STF      | <p>Stop Flag Bit.</p> <p>Each Engine asserts its stop flag (STF) to indicate that it has stopped. Only then the host can assume that the Engine has actually stopped. The eTPU system is fully stopped when the STF bits of both eTPU Engines are asserted. In case of a stop request, the eTPU responds by acknowledging stop only after both eTPU 1 and eTPU 2 have been stopped. Engine only stops when any ongoing thread is complete also in this case.</p> <p>Summarizing Engine stop conditions, which STF reflects:</p> <p>STF_1 := (after stop completed) MDIS_1   device stop request.</p> <p>STF_2 := (after stop completed) MDIS_2   device stop request.</p> <p>STF_1 and STF_2 mean STF bit from engine 1 and STF bit from engine 2, respectively.</p> <p>See Register Reset Values in the chip-specific eTPU information.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |

| 16–17<br>CDFC     | <p>Channel Digital Filter Control.</p> <p>These bits select a digital filtering mode for the channels when configured as inputs for improved noise immunity (refer to the table below). The eTPU has three digital filtering modes for the channels which provide programmable trade-off between signal latency and noise immunity (see <a href="#">Enhanced Digital Filter - EDF</a>). Changing CDFC during eTPU normal input channel operation is not recommended since it changes the behavior of the transition detection logic while executing its operation.</p> <p><b>Table 35-13. Channel digital filter control</b></p> <table> <tr> <th>CDFC</th><th>Selected digital filter</th></tr> <tr> <td>00</td><td>TPU2/3 Two Sample Mode: Using the filter clock which is the system clock divided by (2, 4, 8,..., 256) as a sampling clock (selected by <a href="#">FPSCK</a>), comparing two consecutive samples which agree with each other sets the input signal state. This is the default reset state.</td></tr> <tr> <td>01</td><td>eTPU bypass mode: the input signal is taken unfiltered, also making the channels work on T2/T4 timing mode.<sup>1</sup></td></tr> <tr> <td>10</td><td>eTPU Three Sample Mode: Similar to the TPU2/3 two sample mode, but comparing three consecutive samples which agree with each other sets the input signal state.</td></tr> <tr> <td>11</td><td>eTPU Continuous Mode: Signal need to be stable for the whole filter clock period. This mode compares all the values at the rate of eTPU clock (FCSS=1) or eTPU clock divided by two(FCSS=0), between two consecutive filter clock pulses. Signal needs to be continuously stable for the entire period. If all the values agree with each other, input signal state is updated.</td></tr> </table> <p>1. | 11                | eTPU Continuous Mode: Signal need to be stable for the whole filter clock period. This mode compares all the values at the rate of eTPU clock (FCSS=1) or eTPU clock divided by two(FCSS=0), between two consecutive filter clock pulses. Signal needs to be continuously stable for the entire period. If all the values agree with each other, input signal state is updated.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |      |                         |    |                                                                                                                                                                                                                                                                                              |    |                                                                                                                          |    |                                                                                                                                                                 |    |                                                                                                                                                                                                                                                                                                                                                                                 |

|       | The field determines the location of the microcode entry table for the eTPU functions in SCM (see <a href="#">Entry Points</a> ). The following table shows the entry table base address options.                                                                                                                                                                                                                                                                                                    |                                                             |                                                              |                                                              |       |       |       |       |       |       |       |        |       |       |       |       |       |        |        |       |        |        |

### 35.7.6 eTPU Engine 2 Configuration Register (eTPU\_SCR\_ECR\_ENG2)

This register holds configuration and status fields for engine 2.

#### NOTE

See Register Reset Values in the chip-specific eTPU information.

Address: 0h base + 18h offset = 18h

### \* Notes:

- HLTF field: HLTF field reset value is 1 if, after a reset, the eTPU Nexus debug support is on and a breakpoint request is asserted. Otherwise the reset value is 0.
- MDIS field: Reset value is 0.

## eTPU\_SCR\_ECR\_ENG2 field descriptions

| Field     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
|-----------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0<br>FEND | <p>Force End.</p> <p>FEND assertion terminates any current running thread as if an END instruction have been executed (see <a href="#">Ending Current Thread - END</a>).</p> <p>This bit is self-negating when the thread ends.</p> <p><b>NOTE:</b> Only on rare occasions (e.g., during a long stall, see <a href="#">Microengine Stall</a>) FEND can be read as 1, because it negates as soon as the end begins execution.</p> <p>Writing FEND = 1 is ignored and FEND stays 0 when the microengine is in TST, halted, stopped, or idle (no thread executing).</p> <p>0 Normal operation.</p> <p>1 Ends any ongoing thread.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 1<br>MDIS | <p>Module Disable Bit.</p> <p>When MDIS is set, the Engine shuts down its internal clocks, going into Module Disable Mode. TCR1 and TCR2 cease to increment, and input sampling stops. The Engine asserts the stop flag (STF) bit to indicate that it has stopped. However, the BIU continues to run, and the Host can access all registers except for the channel registers (see channel registers starting with eTPU Channel Configuration-Control registers)</p> <p><b>NOTE:</b> The Timebase registers can still be read with MDIS=1, but writes are ineffective and a Bus Error is issued. Global Channel Registers and SDM can be accessed normally.</p> <p>After MDIS is set, even before STF asserts, data read from the channel registers is not meaningful and writes are ineffective, issuing a Bus Error. When the MDIS bit is asserted while the microcode is executing, the eTPU will stop when the thread is complete.</p> <p>Stop completes on the next eTPU clock after the stop condition is valid.</p> <p><b>NOTE:</b> Once MDIS is switched from 1 to 0 or vice versa, it must not write a different value until STF changes accordingly.</p> <p>The MDIS bit is write-protected when VIS=1.</p> <p>See Register Reset Values in the chip-specific eTPU information.</p> |

| 3<br>STF         | <p>Stop Flag Bit.</p> <p>Each Engine asserts its stop flag (STF) to indicate that it has stopped. Only then the host can assume that the Engine has actually stopped. The eTPU system is fully stopped when the STF bits of both eTPU Engines are asserted. In case of IP-Bus stop, the eTPU system responds by acknowledging stop only after both eTPU 1 and eTPU 2 have been stopped. Engine only stops when any ongoing thread is complete also in this case.</p> <p>Summarizing Engine stop conditions, which STF reflects:</p> <p>STF_1 := (after stop completed) MDIS_1   device stop request.</p> <p>STF_2 := (after stop completed) MDIS_2   device stop request.</p> <p>STF_1 and STF_2 mean STF bit from engine 1 and STF bit from engine 2, respectively.</p> <p>See Register Reset Values in the chip-specific eTPU information.</p> <p>0 Engine is operating.</p> <p>1 Engine has stopped (after the local MDIS bit has been asserted, or after the IP-Bus stop line has been asserted).</p> |
| 4–7<br>Reserved  | <p>Reserved.</p> <p>This field is reserved.</p> <p>This read-only field is reserved and always has the value 0.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| 8<br>HLTF        | <p>Halt Mode Flag.</p> <p>If eTPU Engine entered halt state, this flag is asserted. The flag remains asserted while the microengine is in halt state, even during a single-step or forced instruction execution. See <a href="#">Development support features</a> for further details about entering Halt Mode.</p> <p>0 eTPU Engine is not halted.</p> <p>1 eTPU Engine is halted.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |

|                | <p>FPSCCK controls the prescaling of the clocks used in digital filters for the channel input signals and TCRCLK input, as shown in the table below. Filtering can be controlled independently by each engine, but all input digital filters in the same engine have same clock prescaling. For more details, see <a href="#">Filter clock prescaler</a>.</p> <p>A new value written to FPSCCK only becomes effective when the filter prescaler finishes the current count.</p> <p><b>Table 35-18. | 16–17<br>CDFC  | <p>Channel Digital Filter Control.</p> <p>These bits select a digital filtering mode for the channels when configured as inputs for improved noise immunity (refer to the table below). The eTPU has three digital filtering modes for the channels which provide programmable trade-off between signal latency and noise immunity (see <a href="#">Enhanced Digital Filter - EDF</a>). Changing CDFC during eTPU normal input channel operation is not recommended since it changes the behavior of the transition detection logic while executing its operation.</p> <p><b>Table 35-17. Channel digital filter control</b></p> <table> <tr> <th>CDFC</th><th>Selected digital filter</th></tr> <tr> <td>00</td><td>TPU2/3 Two Sample Mode: Using the filter clock which is the system clock divided by (2, 4, 8,..., 256) as a sampling clock (selected by <a href="#">FPSCCK</a>), comparing two consecutive samples which agree with each other sets the input signal state. This is the default reset state.</td></tr> <tr> <td>01</td><td>eTPU bypass mode: the input signal is taken unfiltered, also making the channels work on T2/T4 timing mode.<sup>1</sup></td></tr> <tr> <td>10</td><td>eTPU Three Sample Mode: Similar to the TPU2/3 two sample mode, but comparing three consecutive samples which agree with each other sets the input signal state.</td></tr> <tr> <td>11</td><td>eTPU Continuous Mode: Signal need to be stable for the whole filter clock period. This mode compares all the values at the rate of eTPU clock (FCSS=1) or eTPU clock divided by two(FCSS=0), between two consecutive filter clock pulses. Signal needs to be continuously stable for the entire period. If all the values agree with each other, input signal state is updated.</td></tr> </table> <p>1. This mode compares all the values at the rate of eTPU clock (FCSS=1) or eTPU clock divided by two(FCSS=0), between two consecutive filter clock pulses. Signal needs to be continuously stable for the entire period. If all the values agree with each other, input signal state is updated. |     |    |     |    |     |     |     |     |

| 10             | eTPU Three Sample Mode: Similar to the TPU2/3 two sample mode, but comparing three consecutive samples which agree with each other sets the input signal state.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |                |                                    |     |                                                                                                                                                                                                                                                                                               |     |                                                                                                                          |     |                                                                                                                                                                 |     |                                                                                                                                                                                                                                                                                                                                                                                 |     |    |     |    |     |     |     |     |
| 11             | eTPU Continuous Mode: Signal need to be stable for the whole filter clock period. This mode compares all the values at the rate of eTPU clock (FCSS=1) or eTPU clock divided by two(FCSS=0), between two consecutive filter clock pulses. Signal needs to be continuously stable for the entire period. If all the values agree with each other, input signal state is updated.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |                |                                    |     |                                                                                                                                                                                                                                                                                               |     |                                                                                                                          |     |                                                                                                                                                                 |     |                                                                                                                                                                                                                                                                                                                                                                                 |     |    |     |    |     |     |     |     |

3. See [T2/T4 channel timing](#).

## 35.8 Timebase memory map and registers

Time Base registers allows configuration and visibility of internally-generated time bases TCR1 and TCR2. There is one of each of these registers for each eTPU Engine.

### NOTE

Writes to these registers issue bus error and are ineffective when MDIS=1. Reads are always allowed.

## eTPU\_TBR memory map

| Address offset (hex) | Register name                                                             | Width (in bits) | Access | Reset value | Section/ page               |

### 35.8.1 eTPU Engine 1 Time Base Configuration Register (eTPU\_TBR\_TBCR\_ENG1)

This register configures several timebase options.

Address: 0h base + 20h offset = 20h

|              | <p>These bits are part of the TCR2 clocking system (see <a href="#">Time bases</a>). They determine the clock source for TCR2 before the prescaler. TCR2 can count on any detected edge of the TCRCLK signal or use it for gating eTPU clock divided by 8. After reset - TCRCLK signal rising edge is selected. TCR2 can also be clocked by the eTPU clock divided by 8. TCR2CTL also determines the TCRCLK edge selected for angle tooth detection in angle mode. See the following table.</p> <p><b>Table 35-24. TCR2 Clock Source</b></p> <table><tr><th>TCR2CTL</th><th>AM = 0<br/>TCR2 Clock before prescaler</th><th>AM &gt; 0<br/>Angle Tooth detection</th></tr><tr><td>000</td><td>Gated DIV8 clock (eTPU clock / 8). In this case, when the external TCRCLK signal is low, the DIV8 clock is blocked, preventing it from incrementing the TCR2 prescaler. When the external TCRCLK signal is high, TCR2 prescaler is incremented at the frequency of the eTPU clock divided by 8.</td><td>Do not use with AM &gt; 0</td></tr><tr><td>001</td><td>Rise transition on TCRCLK signal increments the TCR2 prescaler.</td><td>Rising edge</td></tr><tr><td>010</td><td>Fall transition on TCRCLK signal increments the TCR2 prescaler.</td><td>Falling edge</td></tr><tr><td>011</td><td>Rise or Fall transition on TCRCLK signal increments the TCR2 prescaler.</td><td>Both edges</td></tr><tr><td>100</td><td>DIV8 clock (eTPU clock / 8)</td><td>Do not use with AM &gt; 0</td></tr><tr><td>101</td><td>Do not use with AM=0</td><td>Do not use with AM &gt; 0</td></tr><tr><td>110</td><td>Do not use with AM=0</td><td>No edge<sup>1</sup></td></tr><tr><td>111</td><td>TCR2 frozen, except as STAC client</td><td>Do not use with AM &gt; 0</td></tr></table> <p>1. TCRCLK edges are not detected by the EAC logic, but they can still be detected by the channel 0 logic if AM=01.</p> | TCR2CTL                         | AM = 0<br>TCR2 Clock before prescaler | AM > 0<br>Angle Tooth detection | 000 | Gated DIV8 clock (eTPU clock / 8). | 000          | Gated DIV8 clock (eTPU clock / 8). In this case, when the external TCRCLK signal is low, the DIV8 clock is blocked, preventing it from incrementing the TCR2 prescaler. When the external TCRCLK signal is high, TCR2 prescaler is incremented at the frequency of the eTPU clock divided by 8.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     | Do not use with AM > 0          |                                       |                                 |     |                                                                                                                                                                                                                                                                                                 |                        |     |                                                                 |             |     |                                                                 |              |     |                                                                         |            |     |                             |                        |     |                      |                        |     |                      |                      |     |                                    |                        |

|                  | <p>(eTPU Angle Clock) hardware provides angle information to the channels using the TCR2 bus. When AM is reset (non-angle mode), the EAC operation is disabled, and its internal registers can be used as general purpose. For more information, see <a href="#">EAC - eTPU Angle Counter</a>.</p> <p><b>Table 35-22. AM - Angle Mode Selection</b></p> <table><tr><th>Value</th><th>TCR2 Value</th><th>Tooth signal</th><th>Tooth processing channel</th></tr><tr><td>00</td><td>Timebase (EAC operation disabled)</td><td colspan="2">Not applicable</td></tr><tr><td>01</td><td rowspan="3">Angle Ticks</td><td>TCRCLK input</td><td>0</td></tr><tr><td>10</td><td>Channel 1 input</td><td>1</td></tr><tr><td>11</td><td>Channel 2 input</td><td>2</td></tr></table> <p>If TCR1 or TCR2 is a STAC Bus Client (see <a href="#">STAC interface</a>), the EAC operation is not allowed, and AM must be set to 0.</p> <p><b>NOTE:</b> Changing AM may cause unexpected transition detections on the channel selected by AM, depending on the channel mode and state (see <a href="#">Transition detection and Time Base Capture</a>). If AM must be changed with GTBE=1, the recommended procedure is described in <a href="#">Restarting angle logic</a>.</p> | Value           | TCR2 Value               | Tooth signal | Tooth processing channel | 00 | Timebase (EAC operation disabled) | Not applicable |  | 01 | Angle Ticks | TCRCLK input | 0 | 10 | Channel 1 input | 1 | 11 | Channel 2 input | 2 |
| Value            | TCR2 Value                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    | Tooth signal    | Tooth processing channel |              |                          |    |                                   |                |  |    |             |              |   |    |                 |   |    |                 |   |

| 10–15<br>TCR2P   | <p>Timer Count Register 2 Prescaler Control.</p> <p>These bits are part of the TCR2 clocking system (see <a href="#">Time bases</a>). TCR2 is clocked from the output of a prescaler. The prescaler divides its input by (TCR2P + 1) allowing frequency divisions from 1 to 64. The prescaler input is the eTPU clock divided by 8 (in gated or non-gated clock mode), or Internal Timebase input, or TCRCLK filtered input. This field has no effect on TCR2 in Angle Mode.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |                 |                          |              |                          |    |                                   |                |  |    |             |              |   |    |                 |   |    |                 |   |
| 16–17<br>TCR1CTL | <p>TCR1 Clock/Gate Control.</p> <p>TCR1CTL is part of the TCR1 clocking system (see <a href="#">Time bases</a>). It determines, together with TCR1CS, the clock source for TCR1. TCR1 can count on detected rising edge of the TCRCLK signal, the eTPU clock, or the eTPU clock divided by 2 (see the table in the TCR1CS bit description). After reset TCRCLK signal is selected.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |                 |                          |              |                          |    |                                   |                |  |    |             |              |   |    |                 |   |    |                 |   |
| 18<br>TCR1CS     | <p>TCR1 Clock Source</p> <p>TCR1CS provides the option to double the TCR1 incrementing speed, using eTPU clock as its clock source instead of eTPU clock / 2.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |                 |                          |              |                          |    |                                   |                |  |    |             |              |   |    |                 |   |    |                 |   |

| 24–31<br>TCR1P                                                                                                                            | Timer Count Register 1 Prescaler Control.<br><br>TCR1 is clocked from the output of a prescaler. The input to the prescaler is the internal eTPU clock divided by 2, eTPU clock, or the output of TCRCLK filter. The prescaler divides this input by (TCR1P + 1) allowing frequency divisions from 1 up to 256.                                                                                                                                                                                                                                                                              |         |                                                                         |                             |    |   |                                                                     |    |   |          |    |   |          |    |   |                                                                         |    |   |                                                            |    |   |                                      |

1. TCRCLK edges are not detected by the EAC logic, but they can still be detected by the channel 0 logic if AM=01.

2. This selection must not be used in Angle Mode.

### 35.8.2 eTPU Engine 1 Time Base 1 (TCR1) Visibility Register (eTPU\_TBR\_TB1R\_ENG1)

This register provides visibility of the TCR1 time base for host read access (see [Time bases](#)). This register is read-only. The value of the TCR1 time base shown can be driven by the TCR1 counter or imported from STAC bus, depending on the configuration set in [eTPU Engine 1 STAC Configuration Register \(eTPU\\_TBR\\_STAC\\_ENG1\)](#).

When the external TCRCLK signal is high, TCR2 prescaler is incremented at the frequency of the eTPU clock divided by 8.</td><td>Do not use with AM &gt; 0</td></tr><tr><td>001</td><td>Rise transition on TCRCLK signal increments the TCR2 prescaler.</td><td>Rising edge</td></tr><tr><td>010</td><td>Fall transition on TCRCLK signal increments the TCR2 prescaler.</td><td>Falling edge</td></tr><tr><td>011</td><td>Rise or Fall transition on TCRCLK signal increments the TCR2 prescaler.</td><td>Both edges</td></tr><tr><td>100</td><td>DIV8 clock (eTPU clock / 8)</td><td>Do not use with AM &gt; 0</td></tr><tr><td>101</td><td>Do not use with AM=0</td><td>Do not use with AM &gt; 0</td></tr><tr><td>110</td><td>Do not use with AM=0</td><td>No edge<sup>1</sup></td></tr><tr><td>111</td><td>TCR2 frozen, except as STAC client</td><td>Do not use with AM &gt; 0</td></tr></table> <p>1. TCRCLK edges are not detected by the EAC logic, but they can still be detected by the channel 0 logic if AM=01.</p> | TCR2CTL                         | AM = 0<br>TCR2 Clock before prescaler | AM > 0<br>Angle Tooth detection | 000 | Gated DIV8 clock (eTPU clock / 8). In this case, when the external TCRCLK signal is low, the DIV8 clock is blocked, preventing it from incrementing the TCR2 prescaler. When the external TCRCLK signal is high, TCR2 prescaler is incremented at the frequency of the eTPU clock divided by 8. | Do not use with AM > 0 | 001 | Rise transition on TCRCLK signal increments the TCR2 prescaler. | Rising edge | 010 | Fall transition on TCRCLK signal increments the TCR2 prescaler. | Falling edge | 011 | Rise or Fall transition on TCRCLK signal increments the TCR2 prescaler. | Both edges | 100 | DIV8 clock (eTPU clock / 8) | Do not use with AM > 0 | 101 | Do not use with AM=0 | Do not use with AM > 0 | 110 | Do not use with AM=0 | No edge <sup>1</sup> | 111 | TCR2 frozen, except as STAC client | Do not use with AM > 0 |

When the external TCRCLK signal is high, TCR2 prescaler is incremented at the frequency of the eTPU clock divided by 8.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | Do not use with AM > 0          |                                       |                                 |     |                                                                                                                                                                                                                                                                                                 |                        |     |                                                                 |             |     |                                                                 |              |     |                                                                         |            |     |                             |                        |     |                      |                        |     |                      |                      |     |                                    |                        |
| 001          | Rise transition on TCRCLK signal increments the TCR2 prescaler.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       | Rising edge                     |                                       |                                 |     |                                                                                                                                                                                                                                                                                                 |                        |     |                                                                 |             |     |                                                                 |              |     |                                                                         |            |     |                             |                        |     |                      |                        |     |                      |                      |     |                                    |                        |

| 5–6<br>AM    | <p>Angle Mode Selection.</p> <p>This field enables the Enhanced Angle Counter logic to generate angle information (see <a href="#">EAC - eTPU Angle Counter</a>), and also select the tooth signal input and the channel used to process it, as shown in the following table. When EAC is not disabled by AM and neither TCR1 nor TCR2 are STAC Clients, the EAC (eTPU Angle Clock) hardware provides angle information to the channels using the TCR2 bus. When AM</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |                                 |                                       |                                 |     |                                                                                                                                                                                                                                                                                                 |                        |     |                                                                 |             |     |                                                                 |              |     |                                                                         |            |     |                             |                        |     |                      |                        |     |                      |                      |     |                                    |                        |

| 10–15<br>TCR2P   | <p>Timer Count Register 2 Prescaler Control.</p> <p>These bits are part of the TCR2 clocking system (see <a href="#">Time bases</a>). TCR2 is clocked from the output of a prescaler. The prescaler divides its input by (TCR2P + 1) allowing frequency divisions from 1 to 64. The prescaler input is the eTPU clock divided by 8 (in gated or non-gated clock mode), or Internal Timebase input, or TCRCLK filtered input. This field has no effect on TCR2 in Angle Mode.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |                 |                          |              |                          |    |                                   |                |  |    |             |              |   |    |                 |   |    |                 |   |
| 16–17<br>TCR1CTL | <p>TCR1 Clock/Gate Control.</p> <p>TCR1CTL is part of the TCR1 clocking system (see <a href="#">Time bases</a>). It determines, together with TCR1CS, the clock source for TCR1. TCR1 can count on detected rising edge of the TCRCLK signal, the eTPU clock, or the eTPU clock divided by 2 (see the table in the TCR1CS bit description). After reset TCRCLK signal is selected.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |                 |                          |              |                          |    |                                   |                |  |    |             |              |   |    |                 |   |    |                 |   |
| 18<br>TCR1CS     | <p>TCR1 Clock Source</p> <p>TCR1CS provides the option to double the TCR1 incrementing speed, using eTPU clock as its clock source instead of eTPU clock / 2.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |                 |                          |              |                          |    |                                   |                |  |    |             |              |   |    |                 |   |    |                 |   |

| 24–31<br>TCR1P                                                                                                                            | Timer Count Register 1 Prescaler Control.<br><br>TCR1 is clocked from the output of a prescaler. The input to the prescaler is the internal eTPU clock divided by 2, eTPU clock, or the output of TCRCLK filter. The prescaler divides this input by (TCR1P + 1) allowing frequency divisions from 1 up to 256.                                                                                                                                                                                                                                                                              |         |                                                                         |                             |    |   |                                                                     |    |   |          |    |   |          |    |   |                                                                         |    |   |                                                            |    |   |                                      |

1. TCRCLK edges are not detected by the EAC logic, but they can still be detected by the channel 0 logic if AM=01.

2. This selection must not be used in Angle Mode.

### 35.8.6 eTPU Engine 2 Time Base 1 (TCR1) Visibility Register (eTPU\_TBR\_TB1R\_ENG2)

This register provides visibility of the TCR1 time base for host read access (see [Time bases](#)). This register is read-only. The value of the TCR1 time base shown can be driven by the TCR1 counter or imported from STAC bus, depending on the configuration set in [eTPU Engine 2 STAC Configuration Register \(eTPU\\_TBR\\_STAC\\_ENG2\)](#).

|------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 8–10<br>Reserved | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| 11–15<br>MONCHAN | Monitored Channel.<br><br>When the latency monitor is configured for channel mode, this field selects which channel has the latency monitored. MONCHAN has no meaning in priority mode.<br><br><b>NOTE:</b> MONCHAN must only be changed when the Latency Monitor is in disabled mode.                                                                                                                                                                                                                                                   |
| 16–31<br>MAXLAT  | Maximum Latency.<br><br>This field specifies the maximum latency monitored, in microcycles, before a latency timeout. If MAXLAT=0, the latency keeps on being counted and measured, but the comparison with MAXLAT asserts neither the LTO1/2 fields in <a href="#">eTPU Module Configuration Register (eTPU_SCR_MCR)</a> nor issues a Global Exception. See <a href="#">Latency Monitor</a> for the detailed latency timeout description.<br><br><b>NOTE:</b> MAXLAT must only be changed when the Latency Monitor is in disabled mode. |

## 35.10.4 eTPU Latency Monitor Measure Register for Engine 2 (eTPU\_LMR\_LMnMR\_ENG2)

This register holds the latency measured value.

Address: 0h base + C4h offset + (8d × i), where i=0d to 5d

**35.11.2 eTPU Data Error Injection Address Register (eTPU\_MESR\_DEIAR)**

This register holds the address where error is to be injected into the SDM read data path. The two least significant bits are 0 (read-only), so that the address is always word-aligned.

**NOTE**

This register must only be modified when [HDEIE](#) and [MDEIE](#) are both negated.

Address: 0h base + 104h offset = 104h

**35.11.5 eTPU Data Error Report Address Register (eTPU\_MESR\_DERAR)**

This register holds the address where the last non-correctable error was detected from the SDM. It also captures the address of the last correctable error detected, as long as [DNCERR](#) is 0. The two least significant bits are 0 (read-only), so that the address is always word-aligned.

Address: 0h base + 110h offset = 110h

| 0–1<br>ERR_ACC     | Error Access Source Indication.<br><br>This two-bit field indicates the source of the access when the error occurred.<br><br>00 Host - direct access<br>01 Engine 1<br>10 Engine 2<br>11 CDC                                                                                                                                                                                                                |
| 2<br>Reserved      | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                    |
| 3–7<br>ERR_CHANNEL | Error Channel Access Indication.<br><br>This field holds the number of the channel being serviced (not necessarily CHAN) when the error occurred. Its content is meaningful only when the field ERR_ACC indicates Engine 1 or Engine 2.                                                                                                                                                                     |
| 8–17<br>Reserved   | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                    |
| 18–29<br>ERR_ADDR  | Error Address.<br><br>ERR_ADDR holds the (word) address where the last captured SDM read error was detected. The last captured error is a non-correctable one if <b>DNCERR</b> =1, or a correctable one if <b>DNCERR</b> =0 and <b>DCERR</b> =1. The field is meaningless if both <b>DNCERR</b> and <b>DCERR</b> are 0. For more information on error detection, see <a href="#">Memory error support</a> . |
| 30–31<br>Reserved  | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                    |

**35.11.6 eTPU Data Error Report Data Register (eTPU\_MESR\_DERDR)**

This register holds the data read with the last non-correctable error detected from the SDM. It also captures the data of the last correctable error read detection, as long as **DNCERR** is 0. In both cases, the data is captured after the error correction logic. The data is meaningless if both **DNCERR** and **DCERR** are 0. For more information on error detection, see [Memory error support](#).

**NOTE**

Data is sampled before the error correction logic.

Address: 0h base + 114h offset = 114h

**eTPU\_MESR\_DERSR field descriptions (continued)**

| Field | Description                                                                                                                                                                                                                                                                                                          |
|-------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|       | SYND0 holds the syndrome of an error detected in the SDM read data path, as defined in the “Error Correction Code (ECC) and Syndrome Definition” section. The field is meaningless if both <b>DNCERR</b> and <b>DCERR</b> are 0. For more information on error detection, see <a href="#">Memory error support</a> . |
|       | <b>NOTE:</b> Syndrome fields which have their respective BE bits negated are not meaningful.                                                                                                                                                                                                                         |

**35.11.8 eTPU Memory Error Status Register (eTPU\_MESR\_MESR)**

This register gathers status bits of both SCM and SDM error detection and correction support.

Address: 0h base + 120h offset = 120h

### 35.11.9 eTPU Code Error Injection Address Register (eTPU\_MESR\_CEIAR)

This register holds the address where error is to be injected into the SCM read data path. The two least significant bits are 0 (read-only), so that the address is always word-aligned.

#### NOTE

This register must only be modified when [CEIE](#) is negated.

Address: 0h base + 124h offset = 124h

35.11.10 eTPU Code Error Injection Data Pattern Register (eTPU\_MESR\_CEIDPR)

This register is used to specify the bits in which error is injected into the SCM read data path.

NOTE

This register must only be modified when CEIE is negated.

Address: 0h base + 128h offset = 128h

eTPU\_MESR\_CEIDPR field descriptions

| Field         | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
|---------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–31<br>DFLIP | <p>Data Flip bits.</p> <p>Each bit corresponds to a bit in the actual data read from the SCM address defined in <a href="#">eTPU Code Error Injection Address Register (eTPU_MESR_CEIAR)</a>, specifying whether it should be inverted or not. The inversion only occurs if the SCM error injection is enabled by <a href="#">CEIE</a>. The inversion only occurs if the SCM error injection is enabled by <a href="#">CEIE</a> . For more information on error injection, see <a href="#">Error injection</a> .<br><br>0 Parity data bit is not inverted.<br>1 Parity data bit is inverted. |

**35.11.12 eTPU Code Error Report Address Register (eTPU\_MESR\_CERAR)**

This register holds the address where the last non-correctable error was detected from the SCM. It also captures the address of the last correctable error detected, as long as [CNCERR](#) is 0. The two least significant bits are 0 (read-only), so that the address is always word-aligned.

Address: 0h base + 130h offset = 130h

**35.11.13 eTPU Code Error Report Data Register (eTPU\_MESR\_CERDR)**

This register holds the data read with the last non-correctable error detected from the SCM. It also captures the data of the last correctable error read detection, as long as **CNCERR** is 0. In both cases, the data is captured after the error correction logic. The data may be meaningless if both **CNCERR** and **CCERR** are 0. For more information on error detection, see [Memory error support](#).

**NOTE**

CODE is sampled before the error correction logic.

Address: 0h base + 134h offset = 134h

## 35.12 Global Channel memory map and registers

The registers in this section group, by type, the interrupt status and enable bits from all the channels. This organization eases management of all channels or groups of channels by a single interrupt handler routine. These bits, except the service and watchdog status, are mirrored in the individual channel registers, grouped by channel.

**eTPU\_GCR memory map**

| Address offset (hex) | Register name                                                                                    | Width (in bits) | Access | Reset value | Section/ page                 |
|----------------------|--------------------------------------------------------------------------------------------------|-----------------|--------|-------------|-------------------------------|

35.12.1 eTPU Channel Interrupt Status Register for Engine 1 (eTPU\_GCR\_CISR\_ENG1)

This register groups the host interrupt status from all channels. These bits are mirrored from the Channel Status Control register (see [eTPU Channel n Status Control Register for Engine 1 \(eTPU\\_CCCR\\_CnSCR\\_ENG1\)](#)) and the Host must write 1 to clear a status bit.

For details about interrupts, see [Interrupts and data transfer requests](#).

Address: 0h base + 200h offset = 200h

| 0–31<br>SRn | <p>Pending Service Request n.</p> <p>Indicates a pending Service Request for channel n.</p> <p>Pending SR status is a logic OR of all service requests pending: if only HSR is active, SRn clears only at the end of the thread. SRn clear due to the other request sources is microcode dependent.</p> <p><b>NOTE:</b> The pending service status bit for a channel is 1 when a Service Request is pending, even if the Channel is disabled (CPRn = 0).</p> <p><b>NOTE:</b> There can be a delay of one clock between writing HSR greater than 0 in <a href="#">eTPU Channel n Host Service Request Register for Engine 2 (eTPU_CCCR_CnHSRR_ENG2)</a> of a channel and its respective bit being asserted in eTPU_GCR_CPSSR_ENG2.</p> <p>0 No Service Request pending for channel n.</p> <p>1 Pending Service Request for channel n.</p> |

35.12.17 eTPU Channel Service Status Register for Engine 1  
(eTPU\_GCR\_CSSR\_ENG1)

This register holds the current channel service status on whether it is being serviced or not (see [Functions and threads](#)). Only one bit may be asserted in this register at a given time. When no channel is being serviced, the register read value is 0x0000\_0000. This register is read-only and can be read during normal eTPU operation for monitoring the scheduler activity.

NOTE

Channel Service Status does not always reflect decoding of the CHAN register (see [CHAN Register](#)), since the latter can be changed by the service thread microcode.

Address: 0h base + 290h offset = 290h

35.12.18 eTPU Channel Service Status Register for Engine 2  
(eTPU\_GCR\_CSSR\_ENG2)

This register holds the current channel service status on whether it is being serviced or not (see [Functions and threads](#)). Only one bit may be asserted in this register at a given time. When no channel is being serviced, the register read value is 0x0000\_0000. This read-only register can be read during normal eTPU operation for monitoring the scheduler activity.

NOTE

Channel Service Status does not always reflect decoding of the CHAN register (see [CHAN Register](#)), since the latter can be changed by the service thread microcode.

35.13 Channel Configuration Control memory map and registers

Each channel has a group of 3 registers used to control, configure and check status of that channel as shown in the following table. This organization eases individual channel management.

Table 35-121. Channel registers structure

| Channel offset | Register name                                                      |
|----------------|--------------------------------------------------------------------|
| 0x00           | eTPU_CCCR_CnCR_ENGm - eTPU Channel Configuration Register          |
| 0x04           | eTPU_CCCR_CnSCR_ENGm - eTPU Channel Status/Control Register        |
| 0x08           | eTPU_CCCR_CnHSRR_ENGm - eTPU Channel Host Service Request Register |
| 0x0C           | Reserved                                                           |

One contiguous area is used to map all channel registers of each eTPU engine as shown in the following table.

**Table 35-122. Channel registers mMap**

| Offset | Registers structure                   |
|--------|---------------------------------------|
| 0x400  | eTPU 1 Channel 0 Registers Structure  |
| 0x410  | eTPU 1 Channel 1 Registers Structure  |
| 0x420  | eTPU 1 Channel 2 Registers Structure  |
| 0x430  | ----                                  |
| 0x5E0  | eTPU 1 Channel 30 Registers Structure |
| 0x5F0  | eTPU 1 Channel 31 Registers Structure |
| 0x600  | RESERVED                              |
| 0x800  | eTPU 2 Channel 0 Registers Structure  |
| 0x810  | eTPU 2 Channel 1 Registers Structure  |
| 0x820  | ----                                  |
| 0x9E0  | eTPU 2 Channel 30 Registers Structure |
| 0x9F0  | eTPU 2 Channel 31 Registers Structure |
| 0xA00  | RESERVED                              |

There are 64 structures defined, one for each available channel in the eTPU System (32 for each Engine). The base address for the structure presented can be calculated by using the following equation:

$\text{Channel\_Register\_Base} = \text{eTPU\_Engine\_Channel\_Base} + (\text{channel\_number} * 0x10)$ ,  
where:

- eTPU\_Engine\_Channel\_Base = eTPU\_Base + 0x400 for Engine 1.
- eTPU\_Engine\_Channel\_Base = eTPU\_Base + 0x800 for Engine 2.

#### eTPU\_CCCR memory map

| Address offset (hex) | Register name                                                                     | Width (in bits) | Access | Reset value                 | Section/page                 |

### 35.13.1 eTPU Channel n Configuration Register for Engine 1 (eTPU\_CCCR\_CnCR\_ENG1)

This register gathers configurations set individually per channel.

Address: 0h base + 400h offset + (16d × i), where i=0d to 31d

**eTPU\_CCCR\_CnCR\_ENG1 field descriptions (continued)**

| Field             | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
|-------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                   | 0 Use PSTI for Entry Point selection.<br>1 Use PSTO for Entry Point selection.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 7<br>ETCS         | Entry Table Condition Select.<br><br>This bit determines the channel condition encoding scheme that selects, according to channel conditions, the Entry Point to be taken in an Entry Table. ETCS value has to be compatible with the function chosen for the channel, selected in field CFS. Two condition encoding schemes are available. For details about Entry Table and condition encoding schemes, see <a href="#">Entry Points</a> .<br><br>0 Select Standard Entry Table Condition encoding scheme.<br>1 Select Alternate Entry Table Condition encoding scheme. |
| 8–10<br>Reserved  | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| 11–15<br>CFS      | Channel Function Select.<br><br>This field defines the function to be performed by the channel (see <a href="#">Functions and threads</a> ). The Function assigned to the channel has to be compatible with the channel condition encoding scheme, selected by field ETCS.                                                                                                                                                                                                                                                                                                |
| 16<br>ODIS        | Output Disable.<br><br>This bit enables the channel to have its output forced to the value opposite to OPOL when the output disable input signal corresponding to the channel group that it belongs is active (see <a href="#">eTPU channel output disable signals</a> and <a href="#">Figure 35-305</a> ).<br><br>0 Turns off the output disable feature for the channel.<br>1 Turns on the output disable feature for the channel.                                                                                                                                      |
| 17<br>OPOL        | Output Polarity.<br><br>Determines the output signal polarity. The activation of the output disable signal forces, when enabled by the ODIS bit, the channel output signal to the opposite of this polarity (see <a href="#">Figure 35-305</a> ).<br><br>0 Output active low (output disable drives output to high).<br>1 output active high (output disable drives output to low).                                                                                                                                                                                       |
| 18–20<br>Reserved | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| 21–31<br>CPBA     | Channel n Parameter Base Address.<br><br>The value of this field times 8 specifies the SDM parameter base host (byte) address for channel n (2-parameter granularity; see <a href="#">SDM organization</a> ). As seen by the Host, the channel parameter base (byte) address is (without parameter sign extension) $eTPU\_Base + 0x8000 + CPBA * 8$ or (with parameter sign extension), $eTPU\_Base + 0xC000 + CPBA * 8$ .                                                                                                                                                |

35.13.2 eTPU Channel n Status Control Register for Engine 1 (eTPU\_CCCR\_CnSCR\_ENG1)

This register gathers the interrupt status bits of the channel and the Function Mode definition (read-write). Bits CIS, CIOS and DTRS for each channel can be also accessed from [eTPU Channel Interrupt Status Register for Engine 1 \(eTPU\\_GCR\\_CISR\\_ENG1\)](#), [eTPU Channel Interrupt Overflow Status Register for Engine 1 \(eTPU\\_GCR\\_CIOSR\\_ENG1\)](#) and [eTPU Channel Data Transfer Request Status Register for Engine 1 \(eTPU\\_GCR\\_CDTRSR\\_ENG1\)](#). Host must write 1 to clear a status bit.

Address: 0h base + 404h offset + (16d × i), where i=0d to 31d

|-------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 11–15<br>CFS      | Channel Function Select.<br><br>This field defines the function to be performed by the channel (see <a href="#">Functions and threads</a> ). The Function assigned to the channel has to be compatible with the channel condition encoding scheme, selected by field ETCS.                                                                                                                                                           |
| 16<br>ODIS        | Output Disable.<br><br>This bit enables the channel to have its output forced to the value opposite to OPOL when the output disable input signal corresponding to the channel group that it belongs is active (see <a href="#">eTPU channel output disable signals</a> and <a href="#">Figure 35-305</a> ).<br><br>0 Turns off the output disable feature for the channel.<br>1 Turns on the output disable feature for the channel. |
| 17<br>OPOL        | Output Polarity.<br><br>Determines the output signal polarity. The activation of the output disable signal forces, when enabled by the ODIS bit, the channel output signal to the opposite of this polarity (see <a href="#">Figure 35-305</a> ).<br><br>0 Output active low (output disable drives output to high).<br>1 output active high (output disable drives output to low).                                                  |
| 18–20<br>Reserved | Reserved.<br><br>This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                             |
| 21–31<br>CPBA     | Channel n Parameter Base Address.<br><br>The value of this field times 8 specifies the SDM parameter base host (byte) address for channel n (2-parameter granularity; see <a href="#">SDM organization</a> ). As seen by the Host, the channel parameter base (byte) address is (without parameter sign extension) $eTPU\_Base + 0x8000 + CPBA * 8$ or (with parameter sign extension), $eTPU\_Base + 0xC000 + CPBA * 8$ .           |

35.13.5 eTPU Channel n Status Control Register for Engine 2 (eTPU\_CCCR\_CnSCR\_ENG2)

This register gathers the interrupt status bits of the channel and the Function Mode definition (read-write). Bits CIS, CIOS and DTRS for each channel can be also accessed from [eTPU Channel Interrupt Status Register for Engine 2 \(eTPU\\_GCR\\_CISR\\_ENG2\)](#), [eTPU Channel Interrupt Overflow Status Register for Engine 2 \(eTPU\\_GCR\\_CIOSR\\_ENG2\)](#) and [eTPU Channel Data Transfer Request Status Register for Engine 2 \(eTPU\\_GCR\\_CDTRSR\\_ENG2\)](#). Host must write 1 to clear a status bit.

Address: 0h base + 804h offset + (16d × i), where i=0d to 31d

| Field             | Description                                                                                                                                                                                                                                                                                                                                                                                         |
|-------------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                   | This bit shows the current value driven in the channel output signal, including the effect of the external output disable feature (see <a href="#">eTPU channel output disable signals</a> ). If the channel input and output signals are connected to the same pad, OPS reflects the value driven to the pad. This is not necessarily the actual pad value, which drives the value in the bit IPS. |

## 35.14 Shared Subsystem Integration memory map and registers

Shared Subsystems Integration Registers configure aspects of how the shared modules interface with the eTPU. There is one integration register for each subsystem unit, which can be, depending on the specific subsystem, a whole IP module, a sub-module, or a channel within a module. For more details, see [Shared Subsystems support](#).

## 35.15 Functional description

### 35.15.1 Functions and threads

eTPU processing is event-driven, in the sense that eTPU microcode only runs to service a request from an event. Service Requests may result from the occurrence of any of the following events:

- Host CPU writing a non-zero value to the channel HSR (Host Service Request) field in [eTPU Channel n Host Service Request Register for Engine 1 \(eTPU\\_CCCR\\_CnHSRR\\_ENG1\)](#) and [eTPU Channel n Host Service Request Register for Engine 2 \(eTPU\\_CCCR\\_CnHSRR\\_ENG2\)](#).
- Occurrence of a time base match, an input signal transition, or a specific combination of them (depending on the Channel Mode currently configured).
- A Link Service Request.

A given event is always associated to only one Channel:

- There is one HSR register field for each Channel
- Each signal is associated with only one Channel, which has its own Match registers and independent mode configuration.
- Each Link Service Request can have only one Channel as a target.

Service Request processing is done by a set of microengine routines. A set of related routines that implement a specific channel application is called a **Function**. One or more Functions reside on SCM, limited only by the SCM space available, size of microcode Functions and the number of entry points available. Each Engine can be controlled by up to 32 Functions at a time.

A Function can be assigned to several channels, but only one Function can be assigned to a given Channel at a time. This is defined by the Host through the Channel Configuration Registers (see [Channel Configuration Control memory map and registers](#)).

The term **Thread** will be used hereafter to refer to a service routine of a Function, or its execution. A Thread is constructed of a specific number of microinstructions, typically the code necessary to calculate the next phase of waveform to be input to, or output from, a given channel. Once a Thread begins, its execution cannot be interrupted. A Thread normally finishes when an END microinstruction is executed.

A given Thread is selected and called by the Scheduler depending on the following:

- the type of event that generated the service request.

## Functional description

- the Function assigned to the target channel.
- target channel pin state.
- the state of the channel logic.
- the priority assigned to the target channel, relative to the priorities of other channels with pending service requests

The mechanism to select a thread based on the channel Function and type of event is described in the [Entry Points](#).

The priority mechanism that determines the order of Thread execution amongst pending service requests is described in [Scheduler](#).

### 35.15.1.1 Entry Points

#### 35.15.1.1.1 Entry Table

Each Thread has its **Entry Point**, which contains the SCM address of its first instruction, besides other information. For a complete Entry Point description, see [Entry Point format](#).

Once the Scheduler chooses a channel among pending Service Requests, the Entry Point is taken from an **Entry Table**, based on the Function assigned for the channel and other conditions. Entry Table layout is shown in the following figure.

Figure 35-291. Entry Table

The Entry Table is organized by Functions. Each Function can have up to 32 Entry Points of 16 bits each, corresponding to 32 possible Threads per Function. Each Entry Point location in the table corresponds to a combination of events and channel states (see [Entry Point address generation](#)). A single Thread can be associated to more than one combination, having its Entry Point repeated in the table. Each 32-bit word in the Entry Table holds two Entry Points.

Note that the Entry Table can be placed in any SCM address multiple of the Entry Table size, determined by the ETB field in [eTPU Engine 1 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG1\)](#) and [eTPU Engine 2 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG2\)](#). However, it is recommended to place the Entry Table at the start of the SCM to get continuous code memory and to ease the eventual migration of the code from larger parts down to smaller ones without rearranging the binary image, but this is not a restriction. Unused Entry Points may be used for microcode, so this organization extends the microcode continuous area to the unused area of the Entry Table. For this purpose, Function numbers should be selected from 0 up to 31. If, for example, only 8 functions are implemented, only the Entry Table locations for Functions 0 to 7 are used, and the Entry Table locations for functions 8 to 31 can be used as microinstruction memory (adding extra continuous 1536 bytes for microprogram usage).

One way of implementing different sets of Functions is having more than one Entry Table, and configuring the eTPU with the appropriate one for the application by changing the ETB field in [eTPU Engine 1 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG1\)](#) and [eTPU Engine 2 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG2\)](#). Note that the Engines can use different Entry Tables, with or without the same set of Functions.

### 35.15.1.1.2 Entry Point address generation

The Entry Point address within the Entry Table is determined by the Function assigned to the Channel, the state of the Channel, the type of event, and the condition encoding scheme. Together with the Entry Table base address, they form the Entry Point Address at the SCM, as shown in the following figure.

**Figure 35-292. Entry Point Address (host address offset)**

The type of event and channel state are coded in the Encoded Channel Conditions field C4-C0, according to one of two encoding schemes:

- Standard Entry Table Condition encoding scheme, shown in [Table 35-333](#), which privileges Host Service Requests.
- Alternate Entry Table Condition encoding scheme, shown in [Table 35-334](#), which focus on other events and state decoding.

The events that take part on condition encoding generate a Service Request, and have four origins:

1. Match Recognition (caused by greater/equal match, or equal-only, between the value TCR1/2 and the value stored in the channel match registers). eTPU channels support single and double match in various modes of match recognition; see [Match Recognition](#).
2. Transition Detect Service Request (channel input signal transition detection of a selected edge). The eTPU channels support single and double transition, which together with the double match options provide various modes of transition detection; see [Transition detection and Time Base Capture](#).

3. Channel Linking Service Request (microcode writing the channel number to the LINK register). Link service request allows one channel to activate another (see [Channel Link](#)). Links may also come from Shared Subsystem units (see [Shared Subsystems support](#)).
4. Host Service Request (Host writes a non-zero value to the HSR bits of the channel; see [Host Service Requests](#)).

### Note

Even if a Transition or Match Service Request is inhibited (by channel mode/state or SRI), the Transition Detection and Match Recognition are taken into account for condition encoding. That is, the MRLA/B and TDLA/B flags are used, not their respective Service Requests.

Columns Host Request Bits, Link Request, MatchA/TransB, and MatchB/TransA determine the type of event. A non-zero value in these columns represents the recognition of the event, while "x" indicates that its recognition is irrelevant. Values 1 and 0 mean that event was recognized or not, respectively. Note that Match and Transition events may occur and not be recognized, and in this case it assumes value 0 for the condition encoding. The recognition of such an occurred event depends on the channel mode assigned and other conditions, as described in [Enhanced Channels](#).

The **Host Service Request Bits** column refers to the value written by the Host CPU to the Host Service Request Registers ([eTPU Channel n Host Service Request Register for Engine 1 \(eTPU\\_CCCR\\_CnHSRR\\_ENG1\)](#) and [eTPU Channel n Host Service Request Register for Engine 2 \(eTPU\\_CCCR\\_CnHSRR\\_ENG2\)](#)) of the Channel being serviced. Note that the bits on this row are coded (3-bit representation). If the value of HSR is not zero, then the Host actually requested service.

The **Link Request** column refers to the occurrence of a Channel Link or SSS Link requests.

The **MatchA/TransB** column refers to the recognition of either a Match event specified by MatchA channel register or the detection of a channel input signal event specified by the IPACB configuration register (see [Pin Control Registers](#)).

The **MatchB/TransA** column refers to the recognition of either a Match event specified by MatchB channel register or the detection of a channel input signal event specified by the IPACA configuration register (see [Pin Control Registers](#)).

For the channel input signal, MatchA and MatchB provide double timeout conditions which depend on the channel mode programming (see [Channel Modes](#)). If the channel is used for output only, there are no transition detections, so the MatchB/TransA column

represents only Match B, and MatchA/TransB column the Match A. In this case Match A and Match B are separated to give better state resolution in double match output functions. For more information about channel requests refer to [Enhanced Channels](#).

Besides those events, the following channel state conditions help to determine the Entry Point:

1. Channel Flags 0 and 1: these are channel-internal flags (not in SDM) associated with a channel. Their values are set by microcode (see [Channel flags operations](#)).
2. Input Pin state or Output Flip Flop: the state (0 or 1) of the channel input signal after the Enhanced Filter (see [Enhanced Digital Filter - EDF](#)), or the state driven to the output signal. Which one (input or output) is used is selected by the ETPD field in [eTPU Channel n Configuration Register for Engine 1 \(eTPU\\_CCCR\\_CnCR\\_ENG1\)](#) and [eTPU Channel n Configuration Register for Engine 2 \(eTPU\\_CCCR\\_CnCR\\_ENG2\)](#).

The two Entry Table Condition encoding schemes combine events and state conditions differently, as detailed in the following sections.

### 35.15.1.1.3 Standard condition encoding scheme

In this scheme, shown in the following table, all 7 HSR combinations are used and other event type columns are marked "x" when HSR is non-zero, indicating that Host Service Request has priority over any other type of event. However, when an HSR service thread is called (entry numbers 0 to 9), other events may also have been recognized, and it is microcode responsibility to check them.

When HSR is 0, i.e., Host did not issue a Service Request to the channel, the other event conditions, the input signal state and channel flags determine the Entry Point. Note that channel flag 1 does not influence the encoding in this scheme.

**Table 35-333. Standard channel condition encoding scheme**

| No. | Encoded channel conditions [C4-C0] | Host Service Request bits | Link request | MatchA/ TransB | MatchB/ TransA | In/output pin state <sup>1</sup> | Channel Flag1 | Channel Flag0 |
|-----|------------------------------------|---------------------------|--------------|----------------|----------------|----------------------------------|---------------|---------------|
| 0   | 001                                | 00000                     | x            | x              | x              | 0                                | x             | 0             |

| <div style="display: flex; align-items: center;"> <div style="width: 100px; height: 30px; background-color: #cccccc; margin-right: 10px;"></div> <div>Host Service Request</div> </div> |                                    |                           |              |               |               |                                  |               |               |

1. The ETPD field in [CCR\\_ENG1](#) and [CCR\\_ENG2](#) selects between input and output pin state.

#### 35.15.1.1.4 Alternate condition encoding scheme

This scheme is shown in the following table. Because the HSR bits cannot be tested by microcode, only three distinct Host Service Request can be used:

1. HSR=010 or 011, which are coded into the same Entry Points (0 to 3)
2. HSR=100, 101 or 001, which are all coded into Entry Point 4

### 3. HSR=110 or 111, which are both coded into Entry Point 5

The remaining Entry Points use both channel flags for better state decoding, making this scheme better suited for Functions which need more states and/or faster state decoding, without needing many HSRs.

**Table 35-334. Alternate channel condition encoding scheme**

| No. | Encoded channel conditions [C4-C0] | Host Service Request bits | Link request | MatchA/TransB | MatchB/TransA | In/Output pin state <sup>1</sup> | Channel Flag1 | Channel Flag0 |
|-----|------------------------------------|---------------------------|--------------|---------------|---------------|----------------------------------|---------------|---------------|
| 0   | 00000                              | 01x                       | x            | x             | x             | 0                                | x             | 0             |

| 24  | 11000                              | 000                       | x            | 1             | 1             | 0                                | 0             | 0             |
| 25  | 11001                              | 000                       | x            | 1             | 1             | 0                                | 0             | 1             |
| 26  | 11010                              | 000                       | x            | 1             | 1             | 0                                | 1             | 0             |
| 27  | 11011                              | 000                       | x            | 1             | 1             | 0                                | 1             | 1             |
| 28  | 11100                              | 000                       | x            | 1             | 1             | 1                                | 0             | 0             |
| 29  | 11101                              | 000                       | x            | 1             | 1             | 1                                | 0             | 1             |
| 30  | 11110                              | 000                       | x            | 1             | 1             | 1                                | 1             | 0             |

Table continues on the next page...

**Table 35-334. Alternate channel condition encoding scheme (continued)**

| No. | Encoded channel conditions [C4-C0] | Host Service Request bits | Link request | MatchA/TransB | MatchB/TransA | In/Output pin state <sup>1</sup> | Channel Flag1 | Channel Flag0 |
|-----|------------------------------------|---------------------------|--------------|---------------|---------------|----------------------------------|---------------|---------------|
| 31  | 11111                              | 000                       | x            | 1             | 1             | 1                                | 1             | 1             |
|     |                                    | Host Service Request      |              |               |               |                                  |               |               |

1. The ETPD field in [CCR\\_ENG1](#) and [CCR\\_ENG2](#) selects between input and output pin state.

### 35.15.1.1.5 Entry Point format

Entry Point information includes a Preload-Parameter selection field, a Match Enable field, and the first microcode address of the thread. The Entry Point format is illustrated in the following figure.

**Figure 35-293. Entry Point format**

#### PP - Preload Parameter

PP indicates which pair of channel parameters are loaded into registers P and DIOB from the SDM prior to the execution of a thread. Preloading occurs during the time-slot transition period (see [Time Slot Transition](#)).

1 = microengine register P is preloaded from parameter 2 and DIOB from parameter 3.

0 = microengine register P is preloaded from parameter 0 and DIOB from parameter 1.

The parameter numbers are offsets from the channel parameter base address. For more info, see [Parameter Access](#).

#### ME - Match Enable

ME specifies whether match event recognitions are enabled or disabled for the thread associated with the entry point during the thread execution. If they are disabled, a match recognition can only occur after channel service. For more details refer to [Match Recognition](#).

1 = Matches are enabled during the thread.

0 = Matches are disabled during the thread.

The disabling of Match A/B recognition by MEF is dependent on IPACA/B configuration on the serviced channel (see [Pin Control Registers](#)). If IPACA=1xx, Match A is not disabled by ME=0. Likewise, IPACB=1xx overrides the effect of ME on Match B to "always on". If IPACA/B=0xx, Match A/B is disabled for two microcycles during TST (see [Time Slot Transition](#)) and is re-enabled when Entry Point is loaded, if ME=1. Note that if the comparator is in equal-only mode and the time base reaches the value of the Match register during the time that recognition is disabled (beginning of TST, plus whole thread if ME=0), the match recognition is lost. If the comparator is in greater-equal mode, the match event may be recognized after the disabling period if it satisfies the "greater-than" condition.

#### MICROCODE ADDRESS - Starting Microcode Address

This field specifies the microcode address on which the thread is to begin execution.

### 35.15.1.2 Time Slot Transition

The Time Slot Transition period (also called TST for short) is the interval between the servicing of two channels, during which all Channel-specific context is loaded for the new serviced Channel. The primary tasks completed during this period include:

- Set MEF for the TST wait-states, if any.
- Reset MEF for the first two microcycles (after eventual wait-states).
- Update of the CHAN register with the number of the new channel to be serviced.
- Parallel update of ERTA and ERTB from CaptureA and CaptureB registers of the new serviced channel.
- Sampling of the branch conditions of the new channel to be serviced into the branch logic (this means flags TDLA/B, MRLA/B, LSR, FM[1], FM[0], and PSS). The branch conditions are coherent with the timebase capture values sampled into ERTA/B (if MRLA/B, TDLA/B are set at the same time of the sampling, either both old flag state and capture values are sampled, or both new values are sampled).
- Formation of the entry point address.
- Copy the ME bit in the Entry Point into MEF.
- Access to the entry point location and getting the first microinstruction address.
- Preload of two parameters from the SDM into P (32 bits) and DIOB (24 bits).
- Fetch the first instruction of the thread to be executed for the new channel.
- Preset the RAR register value (see [RAR Register](#)).

The preload operation is 32-bit wide for P and 24-bit wide for DIOB. The P register is loaded with all the 32-bit parameter. The DIOB register is loaded with the lower 24-bits of the parameter. The microcode can switch at any time to access the lower 24-bits, upper byte, or all the 32-bits of any parameter in the SDM. Preload of P-DIOB pair of parameters is atomic with respect to Host and CDC accesses, and so are coherent with their dual-parameter coherent transfers. For more details see [Parameter sharing and coherency](#).

No instructions are executed at the Engine where the time slot transition period occurs, but the other Engine can execute normally. Match A/B is unconditionally disabled on the first two TST microcycles, if IPACA/B=0xx (respectively). During the rest of time slot transition, match recognition can be disabled or not, depending on IPACA/B field and ME. See [Match Recognition](#).

Time Slot Transition takes a minimum of 3 microcycles (6 eTPU clocks), which may be extended due to SDM arbitration wait-states for the first preload access (see [SDM arbitration](#)). When no wait-states are received ([Figure 35-294](#)), DIOB is preloaded twice, one for each PP value, and the correct value remains in DIOB when the Entry Point is loaded. [Figure 35-295](#) and [Figure 35-296](#) show the timing for one and two wait-states, respectively.

Registers B, C, D and SR are not altered by TST and keep their values from the previous thread. The values of registers A, MACL and MACH are not guaranteed at the thread start.

Figure 35-294. TST Timing - No Wait-states

Figure 35-295. TST Timing - 1 Wait-State

Figure 35-296. TST Timing - 2 Wait-states

For more information on Channel-specific registers and flags, refer to [Enhanced Channels](#). For more information on P, ERTA/B and DIOB registers refer to [Registers](#).

### 35.15.1.2.1 Thread gap

The MEF timing has changed from previous eTPU/eTPU2 versions, now being reset for two microcycles from the start of TST.<sup>12</sup> Therefore, two consecutive threads with ME=0 serving the same channel could block any match until the end of the second thread (see [Figure 35-294](#)). This could cause latency problems and also break compatibility with legacy code, so the thread transition logic was modified to introduce a one-microcycle gap between consecutive threads servicing the same channel, as shown in the following

12. the new MEF timing is found on all eTPU2 instances starting from the first version with Memory Error Support; all previous eTPU2 versions maintain the former MEF timing (see [Legacy Time Slot Transition Timing](#)).

figure. During the gap MEF is set to one, regardless of the previous or the next entry point ME field. The thread gap is inserted only between threads serving the same channel.

Figure 35-297. Thread gap

### 35.15.1.3 Thread ending

Threads can finish by either:

- an instruction with the END field active (see [Ending Current Thread - END](#)).
- a forced END by host writing to the FEND field in [eTPU Engine 1 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG1\)](#) and [eTPU Engine 2 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG2\)](#).

- a forced END caused by Watchdog timeout (see [Watchdog](#)).
- a forced END caused by a non-correctable memory error (see [Memory error support](#)).

### 35.15.1.4 Watchdog

Each engine has a watchdog mechanism to prevent a thread or a sequence of threads from running too long, impacting the latency of the other channel services. The watchdog is configured through [eTPU Watchdog Timer Register for Engine 1](#) (eTPU\_ER\_WDTR\_ENG1) and [eTPU Watchdog Timer Register for Engine 2](#) (eTPU\_ER\_WDTR\_ENG2). When the watchdog is enabled, an internal counter increments on each microcycle when a thread is executing. If the count is greater than the value specified in the WDCNT field in [eTPU Watchdog Timer Register for Engine 1](#) (eTPU\_ER\_WDTR\_ENG1) and [eTPU Watchdog Timer Register for Engine 2](#) (eTPU\_ER\_WDTR\_ENG2) and a thread is still executing, the watchdog:

1. If the WMO field in [eTPU Watchdog Timer Register for Engine 1](#) (eTPU\_ER\_WDTR\_ENG1) and [eTPU Watchdog Timer Register for Engine 2](#) (eTPU\_ER\_WDTR\_ENG2) is negated, forces an END of the thread, allowing other channels to be serviced
2. Sets the WDS status bit of the serviced channel in [eTPU Watchdog Status Register for Engine 1](#) (eTPU\_GCR\_WDSR\_ENG1) and [eTPU Watchdog Status Register for Engine 2](#) (eTPU\_GCR\_WDSR\_ENG2).
3. If the WMO field in [eTPU Watchdog Timer Register for Engine 1](#) (eTPU\_ER\_WDTR\_ENG1) and [eTPU Watchdog Timer Register for Engine 2](#) (eTPU\_ER\_WDTR\_ENG2) is negated, the channel is disabled, not initiating any thread until its WDS bit is cleared (however, its CPR field in [eTPU Channel n Configuration Register for Engine 1](#) (eTPU\_CCCR\_CnCR\_ENG1) and [eTPU Channel n Configuration Register for Engine 2](#) (eTPU\_CCCR\_CnCR\_ENG2) is not changed).
4. Issues a Global Exception and sets [WDTO1](#) (engine 1) or [WDTO2](#) (engine 2), regardless of the WMO bit state.

If the WMO field in [eTPU Watchdog Timer Register for Engine 1](#) (eTPU\_ER\_WDTR\_ENG1) and [eTPU Watchdog Timer Register for Engine 2](#) (eTPU\_ER\_WDTR\_ENG2) is asserted, the watchdog can be used to monitor the execution time threshold of a thread or thread sequence without interfering with the eTPU code execution.

The watchdog can be configured in one of the following modes, defining how the internal watchdog count is reset:

- **Thread Length Mode:** the watchdog count is reset at the end of each thread.
- **Busy Length Mode:** the watchdog count is reset when the microengine goes idle. A sequence of threads, one right after another, keeps the count running. The counter is also reinitialized when a thread is forced to end, so that a new count begins if another TST initiates at the following microcycle.

The following applies to the watchdog mechanism:

- microcycles during TST and SDM access wait-states (on TST or instruction execution) are counted.
- if the watchdog count equals WDCNT in the last microinstruction (with SDM wait-states or not) of a thread servicing a channel, its WDS bit is not set.
- if the watchdog count expires (gets greater than WDCNT) during the TST, the thread is forced end on its first instruction.
- the watchdog count does not wrap, so that a thread (in thread length mode) or a thread sequence (in busy length mode) that lasts for more than the maximum value of WDCNT does get a forced end.

### **Note**

Watchdog must not be enabled when the microengine enters halt mode.

The counter does not run when the engine is stopped, and resets when the watchdog is disabled.

## **35.15.2 Host interface**

### **35.15.2.1 System configuration**

System Configuration Registers are described in [System Configuration memory map and registers](#). Detailed explanation of the configured functionalities is found throughout [Functional description](#) and a specification for the initial configuration sequence is found in [Configuration sequence](#).

## 35.15.2.2 Interrupts and data transfer requests

### 35.15.2.2.1 Interrupt types and sources

Each one of the eTPU channels can be a source of two requests: **Channel Interrupt** request and **Data Transfer Request**. Channel Interrupts are targeted to a Host CPU. Data Transfer Requests may be targeted to a data transfer module (for example, a DMA controller). Interrupt and Data Transfer registers are used by the Host to enable interrupts and data transfer requests, indicate their status and service them. Interrupt and Data Transfer requests have the same sets of registers and external signals, and are handled in the same way. They differ only by the fact that Data Transfer Requests are also cleared by the assertion of respective DMA completion acknowledge line.

#### Note

Interrupt and Data Transfer requests can be cleared even when Engines are in Module Disable Mode, through the Global Channel Registers, and also DMA completion for Data Transfer requests.

Channel Interrupts and Data Transfer Requests can only be issued by eTPU microcode, through one of the Channel Control instruction fields (see [Channel Interrupt and Data Transfer Requests](#)).

Both Channel Interrupt and Data Transfer requests can be individually enabled for each channel.

eTPU Interrupt and Data Transfer Registers are mirrored in two organizations: grouped by Channel and grouped by type (interrupt status, interrupt enable, data transfer status, data transfer enable). This allows either "channel-oriented" or "bundled channel" Host interrupt service schemes, or a combination of them. For a detailed description, refer to the Channel Register Layout and Global Channel Registers sections.

eTPU can also assert a **Global Exception** interrupt indicating a global illegal state. There are six possible sources for a Global Exception:

- Execution of an illegal instruction by the microengine (see [Illegal instructions](#)). This Global Exception source is flagged by [ILF1](#) and [ILF2](#).
- An SCM signature mismatch detected by the Multiple Input Signature Calculator - MISC. See [SCM Test - Multiple Input Signature Calculator](#). This source is flagged by [SCMMISF](#).

- Microcode request, through microinstruction field CIRC (see [Channel Interrupt and Data Transfer Requests](#)). This Global Exception source is flagged by [MGE1](#) (Engine 1) and [MGE2](#) (Engine 2). The cause of this illegal state is application-dependent. The microcode may write an error code into the SDM to indicate the cause of the exception, for instance.
- A Watchdog timeout, flagged by [WDTO1](#) and [WDTO2](#) (see [Watchdog](#)).
- An SDM or SCM non-correctable error on a microengine or host access, flagged by [SDMERR](#) and [SCMERR](#), respectively (see [Memory error support](#)).
- Bus errors on microengine accesses to the Shared Subsystem Area, flagged by [SSAERR](#) (see [Shared Subsystems support](#)).
- The latency measured by any of either engine's Latency Monitors is greater than the specified maximum, flagged by [LTO1](#) (Engine 1) and [LTO2](#) (Engine 2) (see [Latency Monitor](#)).

Global Exceptions cannot be directly disabled within eTPU, except by disabling its sources (Memory Error, SSS, MISC and microcode), and it is cleared by writing 1 to [GEC](#). Clearing Global Exception clears all Global Exception source status bits (ILF1, ILF2, SCMMISF, MGE1, MGE2, SSAERR, SCMERR, SDMERR). If GEC is written 1 at the same time any of the sources issues a Global Exception, both the interrupt and the status bit of that source remains asserted. The assertion of Global Exception by one of the sources above does not prevent the others from asserting it too, so any number of them, in any combination, can be flagged.

### Note

There can be a race between the clear of a Global Exception and occurrence of a new set condition, such that the set happens just before the clear and cannot be sensed by the Host. Therefore, Global Exception cannot be used as a normal interrupt source. It should only be used for emergency procedures.

Memory Error Correction support (see [Memory error support](#)) has a distinct interrupt source, which can activate on any correctable error occurrence, either to SCM or SDM accesses, but does not activate on non-correctable errors (which assert Global Exception instead). Memory Error Correction interrupt assert when it is enabled through [MECIE](#) (see [eTPU Memory Error Status Register \(eTPU\\_MESR\\_MESR\)](#)) and either DCERR or CCERR in [eTPU Memory Error Status Register \(eTPU\\_MESR\\_MESR\)](#) is asserted. The interrupt is negated when both DCERR and CCERR are negated, or MECIE is negated.

### 35.15.2.2.2 Interrupt and Data Transfer Request overflow

If a Channel Interrupt was issued, its status bit is still set, and microcode issues another Channel Interrupt, the Interrupt Overflow status bit is set for that channel. Interrupt Overflow status can be checked by the Host in the CIOS field of [eTPU Channel n Status Control Register for Engine 1 \(eTPU\\_CCCR\\_CnSCR\\_ENG1\)](#) and [eTPU Channel n Status Control Register for Engine 2 \(eTPU\\_CCCR\\_CnSCR\\_ENG2\)](#), mirrored in [eTPU Channel Interrupt Overflow Status Register for Engine 1 \(eTPU\\_GCR\\_CIOSR\\_ENG1\)](#) and [eTPU Channel Interrupt Overflow Status Register for Engine 2 \(eTPU\\_GCR\\_CIOSR\\_ENG2\)](#). Interrupt Overflow status is not cleared automatically when Interrupt Status is cleared. The same mechanism and respective registers ([eTPU Channel Data Transfer Request Overflow Status Register for Engine 1 \(eTPU\\_GCR\\_CDTROSR\\_ENG1\)](#) and [eTPU Channel Data Transfer Request Overflow Status Register for Engine 2 \(eTPU\\_GCR\\_CDTROSR\\_ENG2\)](#)) are available for Data Transfer Requests.

If interrupt is set and cleared at the same time, set prevails and overflow is not altered (keeps the same state as it was before, asserted or not).

Global Exception has no overflow status.

### 35.15.2.3 Parameter Access

#### 35.15.2.3.1 Parameter Access Widths

From the Host side the SDM address space is mapped in bytes, and each 32-bit parameter occupies 4 contiguous, aligned bytes. The Host can read/write the SDM by 8-, 16-, or 32-bit accesses in aligned addresses.

In 32-bit access, Host can access all 32 bits or only the lower 24 bits with an automatic sign extension (see [Parameter Sign Extension area](#)).

#### 35.15.2.3.2 Parameter Addresses and Endianness

To access parameter number xxx, eTPU Microengine(s) would select address xxx. The Host would add  $(xxx*4)$  to the SDM base address to access the same parameter. For example, parameter 0x101 is seen by the Host in  $(SDM\ base\ address + 0x404)$ . An example of SDM memory map is shown in [Figure 35-298](#). The Host can access the SDM with a 32-bit-wide bus cycle to a four-byte aligned address, 16-bit-wide bus cycle to a two-byte aligned address, or 8-bit wide bus cycle to any byte address.

The address of the 24-bit parameters and the most significant byte depends on the endianness of the MCU. For more details, see the [Endianness](#).

### 35.15.2.3.3 Parameter concurrency

Host accesses to parameters may occur in parallel with eTPU Microengine accesses. Readings taken from a group of parameters while they are being simultaneously updated may lack coherency. eTPU provides mechanisms to ensure parameter coherency in accesses from both Host side and Microengine side, including the use of a coherent dual-parameter transfer mechanism, described in detail on [Parameter sharing and coherency](#).

### 35.15.2.3.4 Parameter Sign Extension area

The SDM address space to the Host is mirrored in a Parameter Sign Extension (PSE) area (see [Table 35-4](#)). Accesses from the Host to the PSE area differ from accesses to the standard SDM address space as follows:

- **Writes:** the most significant byte of the parameters is not written, and the SDM retains the old byte value, regardless of the Host access size.
- **Reads:** the most significant bit of the 24-bit parameter (that is, the MSB of the second most significant 32-bit parameter byte) is repeated in the 8 most significant bits of the read value on all 32-bit reads and most significant 16- and 8-bit reads.

The same parameters written in the standard SDM address space are read from the PSE area with the same offsets, and vice-versa. See [Table 35-429](#) for a reference of the address offsets in big and little endian machines.

This feature relieves the Host from extending the signal of 24-bit eTPU parameters before calculations, and from read-modify-write accesses to modify 24-bit parameters at the SDM.

### 35.15.2.4 SDM organization

The SDM internal partition for channel allocation is dynamic and programmed in the Channel Registers (see [eTPU Channel n Configuration Register for Engine 1 \(eTPU\\_CCCR\\_CnCR\\_ENG1\)](#) and [eTPU Channel n Configuration Register for Engine 2 \(eTPU\\_CCCR\\_CnCR\\_ENG2\)](#)).

The Host application is responsible for allocating a different parameter base address to each channel during the initial eTPU configuration, and to allocate enough parameters for the selected Function, with no unintentional overlapping between parameters of different functions.

Besides channel parameters, global areas may have to be allocated for parameters that are shared by more than one channel, in one or both Engines. Also, temporary parameter areas should be reserved to be used by the coherent parameter transfer mechanisms described in [Parameter sharing and coherency](#), if necessary. An SDM organization example is shown in the following figure.

Figure 35-298. SDM Organization Example (4 KB)

Single-engine eTPU or dual eTPU system may require less parameters than the maximum number provided by the SDM. Since the SDM partition is fully dynamic, there is no limitation of fixed channel addresses, and the reduced array can be fully utilized.

### 35.15.2.5 Host Service Requests

Host CPU can request immediate service from a channel by writing a non-zero value to the Host Service Request register field - HSR (see [eTPU Channel n Host Service Request Register for Engine 1 \(eTPU\\_CCCR\\_CnHSRR\\_ENG1\)](#) and [eTPU Channel n Host Service Request Register for Engine 2 \(eTPU\\_CCCR\\_CnHSRR\\_ENG2\)](#)). There is one HSR field for each channel, so that writing to it generates a Service Request to the respective channel only. A zero value in HSR means no Host Service Request is pending for the channel.

HSR value turns to 000 automatically at the end of microengine service for that channel, but only if the thread started due to an HSR.

The meaning of a non-zero HSR value depends on the Function assigned for the channel. These bits are part of the conditions which select the Function entry point, and cannot be tested by microcode. For more details, refer to [Entry Points](#).

If Host writes HSR=000 when a thread for the same channel is already running, the thread runs until the end and is not aborted. If Host writes HSR>000 when an HSR thread for the same channel is already running, HSR value resets at the end of the thread, and no new HSR will be pending. If HSR is written before its value is resolved by the scheduler during TST, the entry point will obey the new HSR value, and if this new value is 000, no service thread is executed for the HSR.

The scheduling of HSRs is completely asynchronous with Host accesses, and there is no race-free manner to change an HSR value before service thread execution, so generally the safe way is: write HSR>0 only when HSR=0. Error recovery or emergency host procedures may require one to safely abort service and reset channel state when an HSR is already pending or executing. In these cases, the procedure below should be followed:

1. Disable the channel, writing CPR=00 in [eTPU Channel n Configuration Register for Engine 1 \(eTPU\\_CCCR\\_CnCR\\_ENG1\)](#) and [eTPU Channel n Configuration Register for Engine 2 \(eTPU\\_CCCR\\_CnCR\\_ENG2\)](#). That will prevent any pending HSR to be serviced.
2. Check if the channel is currently being serviced, reading its service status bit in [eTPU Channel Service Status Register for Engine 1 \(eTPU\\_GCR\\_CSSR\\_ENG1\)](#) and [eTPU Channel Service Status Register for Engine 2 \(eTPU\\_GCR\\_CSSR\\_ENG2\)](#). If

it is, wait for the time necessary to finish the service pending, or check again until  $HSR == 0$ , or channel service bit in [eTPU Channel Service Status Register for Engine 1 \(eTPU\\_GCR\\_CSSR\\_ENG1\)](#) and [eTPU Channel Service Status Register for Engine 2 \(eTPU\\_GCR\\_CSSR\\_ENG2\)](#) is cleared.

3. Write HSR with the error recover value. This value should, possibly combined with other host-defined flags in SDM or FM bits, initiate a channel reset or error recovery procedure.
4. Re-enable the channel, writing CPR value  $> 0$  in [eTPU Channel n Configuration Register for Engine 1 \(eTPU\\_CCCR\\_CnCR\\_ENG1\)](#) and [eTPU Channel n Configuration Register for Engine 2 \(eTPU\\_CCCR\\_CnCR\\_ENG2\)](#).

### 35.15.2.6 SCM access

Only Host can access SCM as data. Depending on the specific device, SCM may be implemented as a RAM or ROM. This determines Host accesses to the SCM as shown below.

#### 35.15.2.6.1 SCM RAM implementations

When SCM is implemented as RAM, the Host may read or write to SCM by setting [VIS](#) = 1. If  $VIS=0$  and Host tries to access SCM space, a bus error is issued, writes are ineffective and read data is meaningless. Both Engines must be stopped or halted to set  $VIS=1$ .

#### Note

It is necessary to turn [VIS](#) bit on to set software breakpoints (see [Software breakpoints](#)).

#### 35.15.2.6.2 SCM low power

SCM turns off its internal clocks when both Engines are stopped (STF field in [eTPU Engine 1 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG1\)](#) and [eTPU Engine 2 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG2\)](#) asserted), [VIS](#), and [MISC](#) is not enabled ( $SCMMISEN=0$ ). The SCM clocks are automatically turned on if either one of the STF bits is negated or [VIS](#) turns to 1, or [SCMMISEN](#) turns to 1.

SCM clocks are not turned off if any of the Engines is not stopped, even if they are both halted.

The conditions for SCM Clocks and MISC activation are summarized in the following table.

**Table 35-335. SCM clocks and MISC activation**

| STF in<br>eTPU_SCR_ECR_<br>ENG1 | STF in<br>eTPU_SCR_ECR_<br>ENG2 | VIS in<br>eTPU_SCR_MCR | SCMMISEN in<br>eTPU_SCR_MCR | SCM clocks | MISC             |
|---------------------------------|---------------------------------|------------------------|-----------------------------|------------|------------------|
| 0                               | x                               | 0 <sup>1</sup>         | 1                           | On         | On               |
| 0                               | x                               | 0 <sup>1</sup>         | 0                           | On         | off              |
| x                               | 0                               | 0 <sup>1</sup>         | 1                           | On         | On               |
| x                               | 0                               | 0 <sup>1</sup>         | 0                           | On         | off              |
| 1                               | 1                               | 0                      | 0                           | off        | off              |
| 1                               | 1                               | 0                      | 1                           | On         | On               |
| 1 <sup>2</sup>                  | 1 <sup>2</sup>                  | 1                      | 0                           | On         | off              |
| 1 <sup>2</sup>                  | 1 <sup>2</sup>                  | 1                      | 1                           | On         | off <sup>3</sup> |
| 0                               | 0                               | x                      | 0                           | On         | off              |
| 0                               | 0                               | x                      | 1                           | On         | On               |

1. VIS cannot be written 1 if eTPU\_SCR\_ECR\_ENG1[STF]=0 or eTPU\_SCR\_ECR\_ENG2[STF]=0, and both HLTF bits are 0.
2. If VIS=1, neither MDIS can be written 0 nor the Engine leaves Stop Mode, regardless of device stop request.
3. MISC resets and stays so when VIS=1, restarting automatically when VIS goes 0 if SCMMISEN=1.

### 35.15.2.6.3 SCM Off-range data

When read accesses are made, either by the Host or by a microengine, to addresses above the limit corresponding to [SCMSIZE](#), the value read comes from [eTPU SCM Off-range Data Register \(eTPU\\_SCR\\_SCMOFFDATAR\)](#). The Host can program the register at initialization with an opcode value with operations that try to protect or recover the system from runaway code, for instance: terminate the thread, clear channel flags, disable match and transition service requests, issue an interrupt, jump to an error recovery procedure<sup>13</sup>. Writes to unimplemented addresses do not return error and can write on unspecified mirror addresses, so they should be avoided.

### 35.15.2.7 Bus error conditions

Follows a summary of the possible causes of bus errors on host accesses to the eTPU memory space:

- Read or write access to the SCM with [VIS](#) =0.

13. Only part of these suggested operations can be parallelized in a single instruction, see [Microinstruction formats](#).

- Read or write access to the channel registers with eTPU\_SCR\_ECR\_ENG $n$  bits MDIS=1, or bit STF=1 (see [eTPU Engine 1 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG1\)](#) and [eTPU Engine 2 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG2\)](#)).
- Write access to the Time Base Registers with eTPU\_SCR\_ECR\_ENG $n$  bits MDIS=1, or bit STF=1 (see [eTPU Engine 1 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG1\)](#) and [eTPU Engine 2 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG2\)](#)).
- Non-correctable errors in the SCM on reads of any size or writes less than 32-bits wide when CEDD =0.
- Non-correctable errors in the SDM on reads when DEDD =0.
- Accesses to the Shared Subsystem Area, when propagating a bus error issued by the attached subsystem.

### 35.15.3 Scheduler

Every Function is composed of one or more Threads. A Thread consists of a group of instructions that, once begins execution, cannot be interrupted by host or channel events. Each active channel intends to be serviced, being granted time for Thread execution. Since one microengine handles several channels operating concurrently, the Function threads must be executed serially.

The task of the Scheduler is to recognize and prioritize the channels needing service and to grant execution time to each channel. The time given to an individual Thread for execution or service is called a **Time Slot**. The duration of a time slot is determined by the number of instructions executed in the Thread plus SDM wait-states received, and varies in length.

At any time, an arbitrary number of channels can require service. To request service, channel logic, eTPU microcode or Host application notifies the Scheduler by issuing a Service Request.

#### 35.15.3.1 Channel enabling and priority assignment

Every channel is assigned one of three priority levels - high, middle, or low - by the Host CPU, through the Channel Configuration Register field CPR (see [eTPU Channel  \$n\$  Configuration Register for Engine 1 \(eTPU\\_CCCR\\_C \$n\$ CR\\_ENG1\)](#) and [eTPU Channel  \$n\$](#)

[Configuration Register for Engine 2 \(eTPU\\_CCCR\\_CnCR\\_ENG2\)](#)). These registers are also used to disable the channel, which is equivalent to assigning it a "null" priority. In this case, the Scheduler does not grant any of its Service Requests.

It is possible to change the channel priority level or disable it dynamically. If the Host disables a channel when it is currently being serviced, channel service thread will complete. This means that it is possible for the output level of a channel signal to change, or a Host interrupt occur, even after its priority register was written to "null". For instance, if an output transition is scheduled, the transition will occur even after the channel is disabled.

Service requests previously pending or that occur while a channel is disabled remain asserted while the channel is disabled, and are serviced if the channel is enabled again, in due time determined by the priority scheme and concurrent requests from other channels. Channels are disabled after reset, and it is recommended to configure a Host Service Request for initialization of a channel before that channel is enabled to active priority (see [Initialization/application information](#)).

### 35.15.3.2 Channel priority schemes

The Scheduler holds a Service Grant register with one bit for each channel. Once the Scheduler grants a time slot to channel, the Service Grant bit for that channel is asserted in the Service Grant register. When the Service Grant bit of a channel is set, the channel may request new service but is not serviced again before its Service Grant bit is cleared.

When all channels in a same priority level are serviced, their Service Grant bits are cleared at the end of the thread, one eTPU clock before the next serviced channel is calculated, according to the scheme below<sup>14</sup>:

- Clear all grant bits of priority High if all channels of that priority that are requesting have their grant bits in 1.
- Clear all grant bits of priority Medium if all channels of that priority that are requesting have their grant bits in 1.
- Clear all grant bits of priority Low if all channels of that priority that are requesting have their grant bits in 1.
- Clear all grant bits of disabled channels.

---

14. Grant bits are also cleared in the next clock, when the service channel is chosen, or when the microengine is idle, using the same scheme.

This scheme assures that no channel is left with its grant bit forever asserted (preventing it from being serviced again), even if the channel priorities are reassigned during the execution.

Priority level is determined based on the maximum latency desired for each channel. A channel having a Function that requires the most frequent or more immediate service should be allocated a high priority level.

The eTPU employs a **primary** and a **secondary priority scheme**. These two schemes ensure frequent servicing of high-demand Functions and ensure a minimum time allocation to all channels requesting service, regardless of their priority level. The primary scheme prioritizes requesting channels that have different priority levels; the secondary scheme prioritizes requesting channels that have the same priority level.

Initially, a channel requests service and is granted a time slot by the Scheduler: Service Grant bit is asserted. If only high-level channels constantly receive service first because of their priority level, middle- and low-level channels would only be serviced by default, i.e., if no high-level channels request service. To ensure that each priority level receives an opportunity for servicing, every time slot has a fixed priority level that the Scheduler honors first. Divided into sets of seven, time slots are numbered from one to seven. The figure below illustrates the numbered time slots in sets of seven (fields A and B) and identifies their assigned default priority level. The high level has more time slots than the middle and low levels. Out of every seven time slots available, four are assigned to honor high-level channels first, two are assigned to honor middle-level channels first, and one is assigned to honor low-level channels first. Only one request (in each Engine) is serviced per time slot. When no channel requests service and the microengine is idle the priority scheme is initialized to time slot one, to prevent priority inversion on the next request<sup>15</sup>.

---

15. Priority inversion would occur in the following situation: no channel is requesting service, and the current time slot is primarily assigned to a low-priority channel. If the Scheduler was not reset to time slot one and two channels requested service at the same time, one with high priority and the other with low priority, the channel to be serviced would be the low-priority channel.

Figure 35-299. Time Slot Priority levels

### 35.15.3.2.1 Primary Scheme - Priority Among Channels on Different Levels

Although time slot priority assignment is fixed, the servicing priority is not. The primary scheme acknowledges the priority level assigned to a time slot, granting service first to a channel having the same priority. In [Channel priority schemes](#), time slot one has a high-level assignment; therefore, a high-level channel requesting service is recognized first. However, if no high-level channel requests service, the Scheduler recognizes a requesting middle-level channel. If this level has no request, the Scheduler continues to the low-level. If no requests occur, the Scheduler truncates the seven state cycle and starts a new cycle at time slot one, waiting for the first request. Granting service to a different-level channel is called priority passing. The order of passing always gives the highest priority to the assigned level, and the second priority to the higher of the remaining requesting priority levels as shown in the following table.

Table 35-336. Priority Passing

| Assigned Priority Level | Next Priority Level | Next Priority Level |
|-------------------------|---------------------|---------------------|
| High                    | Middle              | Low                 |
| Middle                  | High                | Low                 |
| Low                     | High                | Middle              |

When priority is passed to another level, that level is serviced and the fixed-priority-level sequence is resumed with the next time slot.

**Figure 35-300. Priority Passing Example**

Examples of priority passing are shown in the above figure. Each cycle contains seven time slots (or less if no service request exist). In cycle B, no high-level or middle-level service requests are present before time slot three which is assigned by default to high-level priority. Thus, time slot three is passed to the low level. In cycle B there are also no middle-level service requests before time slot six, so it passes the priority to a requesting high-level channel. During time slot six no more high level requests are left, but two new middle-level requests arrive, and there are also three low level pending service requests. Thus, time slot seven of cycle B and time slot one of cycle C are passed to the middle-level which is the next priority level after high. Time slots two and three of cycle C are passed to the low level which contains the three remaining channel service requests. At time slot three of cycle C the last low level request is serviced, and the Scheduler passes to idle state. At this point the cycle C is truncated and the Scheduler passes to time slot one of cycle D.

### 35.15.3.2.2 Priority passing disabling

The priority passing scheme allows a case where a high priority channel loses to a lower priority one right after another lower priority has been serviced, exemplified in the Cycle D on [Figure 35-300](#). A middle priority channel wins time slot 1 due to priority passing from high to middle. While it is being serviced, two new service requests arrive, one high and one middle priority. The high priority request loses to the middle one on next time slot 2 by default priority assignment.

This priority inversion can be avoided by setting the SPPDIS field in the eTPU\_SCR\_ECR\_ENG $n$  registers (see [eTPU Engine 1 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG1\)](#) and [eTPU Engine 2 Configuration Register \(eTPU\\_SCR\\_ECR\\_ENG2\)](#)), which disables the priority passing mechanism. When priority passing is disabled, at the end of the thread the slot number is incremented until a time slot that matches the priority of one of the requesting channel(s). The time slot advance takes no extra clocks. If no channel requests service, the time slot counter stays at time slot 1. The priority selection scheme with disabled priority passing is summarized in the following table.

**Table 35-337. Priority Passing Disabling**

| At the end of time slot | servicing priority | if any request of priority | service it on time slot | else if any request of priority | service it on time slot | else if any request of priority | service it on time slot |
|-------------------------|--------------------|----------------------------|-------------------------|---------------------------------|-------------------------|---------------------------------|-------------------------|
| 1                       | High               | Medium                     | 2                       | High                            | 3                       | Low                             | 4                       |
| 2                       | Medium             | High                       | 3                       | Low                             | 4                       | Medium                          | 6                       |
| 3                       | High               | Low                        | 4                       | High                            | 5                       | Medium                          | 6                       |
| 4                       | Low                | High                       | 5                       | Medium                          | 6                       | Low                             | 4                       |
| 5                       | High               | Medium                     | 6                       | High                            | 7                       | Low                             | 4                       |
| 6                       | Medium             | High                       | 7                       | Medium                          | 2                       | Low                             | 4                       |
| 7                       | High               | High                       | 1                       | Medium                          | 2                       | Low                             | 4                       |

An example of the priority passing disabling scheme is illustrated in the figure below. The sequence of service requests is the same as in the example of [Figure 35-300](#), and although the time slot incrementing differs, the priorities granted are the same for cycle B. Cycle C has one of the low priority channels serviced before the second middle one. Cycle D, however, no longer has the priority inversion.

In cycle B, after the time slot 2 only a low priority request remains, so the time slot count advances directly to 4, which has a low priority assigned. Time slot keeps on 4 for the next service, as only a low priority request remains also, and only time slot 4 is assigned to low. Two high priority services contend for the next time slot 5 (assigned to High). The second high priority channel is serviced on the next time slot, jumped to 7 because there is no middle request, ending cycle B. Cycle C starts with time slot 2, as there are no high priority requests and two middle and two low ones. After the first middle service, time slot count skips 3 assigned to high (no high requests), and services a low priority channel on time slot 4. It follows the same scheme until there are no other requests and cycle C is truncated, resetting the time slot counter to 1.

Cycle D begins with a middle request, jumping to time slot 2. During this service two requests arrive, one high and one middle. Unlike what happened with priority passing, the next serviced is the high priority channel, as the time slot increments to 3. The second middle priority channel request in cycle D is finally serviced next, on time slot 6.

Figure 35-301. Priority Passing Disabling Example

### 35.15.3.2.3 Secondary Scheme - Priority Among Channels on the Same Level

Because channels can randomly request service, channels having the same priority level will inevitably request service simultaneously. A secondary scheme prioritizes these requests. The Scheduler services channels on each of the three priority levels, beginning with the lowest numbered channel on that level.

### 35.15.3.2.4 Priority Scheme Example

The overall priority scheme simultaneously incorporates both primary and secondary schemes. Combining both schemes in the following example conveys their correlation.

1. One high-priority and one low priority channels request service, while the Scheduler is in time slot one. Having its service request bit asserted, a single high-level channel is granted the time slot, which has high-level priority (primary scheme) and its service grant bit is asserted. At the end of the thread, the service grant bit is negated (no more requests of high priority level channels).

2. The Scheduler proceeds to time slot two, which has middle-level priority; however, no middle-level channel is requesting service. Priority is passed to the high level, but no high-level channel is requesting service; therefore, priority is passed again, and service is granted to the single requesting low-level channel. Once serviced, this channel's grant bit is negated (no more low-level requests).
3. The Scheduler resumes with the fixed-priority sequence on time slot three; however, no channels are requesting service. The Scheduler returns to time slot one, waiting for requests.
4. Two high-level and two middle-level channels simultaneously request service. Being in time slot one which is assigned high priority, the Scheduler finds the lowest numbered high-level channel (secondary scheme) and selects it for service. This channel's service grant bit is asserted.
5. The Scheduler continues to time slot two, which has middle priority (primary scheme), and allocates the slot to the lowest numbered middle-level channel requesting service (secondary scheme). The Scheduler notes the still unserviced middle-level channel and proceeds to time slot three.
6. Time slot three is allocated for high priority. The slot is allocated to the remaining unserviced high-priority channel, and the channel's service grant bit is asserted. The Scheduler checks again at the end of the thread. All service grant bits of high-level requested channels are asserted; therefore, all high-priority channels that requested have been allocated execution time. Under this condition, all service grant bits of the high-level serviced channels are negated. The Scheduler proceeds to time slot four.
7. Time slot four is allocated for low-priority channel; however, no low-level channel is requesting service. Priority is passed to the high level, but no high-level channel is requesting service; therefore, priority is passed again, and service is granted to the remaining middle-level channel which requests service. This channel's service grant bit is asserted. The Scheduler checks again at the end of the thread. All grant bits of middle-level requested channels are asserted; therefore, all middle-priority channels have been allocated execution time. Under this condition, all service grant bits of the middle-level serviced channels are negated. The Scheduler proceeds to time slot five. Meanwhile a low priority channel requests service.
8. Time slot five is allocated for high-priority channels, but there are no more requests from high-priority or middle priority channels. The single low-level channel which required service is granted time slot five. Once serviced, the channel's service grant bit is asserted. Next, the service grant bit is negated (no more requests of low priority level channels).

9. The Scheduler resumes with the fixed-priority sequence on time slot six; however, no channels are requesting service. The Scheduler returns to time slot one and waits for requests.

35.15.3.3 Time slot latency

Latency is the amount of time between a service request and the beginning of service on that channel. The following factors affect latency:

- Number of active channels
- Number of channels on a priority level
- Number of available time slots on a priority level
- Number of microcycles required to execute a thread of a Function
- Number of SDM accesses during execution of a Function thread
- eTPU clock frequency

Each time slot may require a different number of microcycles, depending on the thread of a Function to be executed. This variation is shown in the figure below.

For more details on latency evaluation, see [Estimating Worst Case Latency](#).

Figure 35-302. Time-slot variation

35.15.4 Parameter sharing and coherency

SDM can be concurrently accessed by Host and Microengines (two in a Dual eTPU Engine system). In general, there is no guaranteed order by which a group of parameters is accessed, which may lead to a lack of internal consistency if two or more related parameters are read when only part of them is updated.

eTPU provides mechanisms to guarantee parameter coherency. The most generic mechanisms for Host-eTPU coherency, suitable for any number of parameters, are:

- the use of Transfer Service Thread mechanism.
- the mailbox (or "software semaphore") mechanism.

These mechanisms, described in [Multiple parameter coherency methods](#), use microcode to transfer parameters from temporary buffers in SDM to their definitive locations (or vice-versa). These methods have the disadvantage of wasting processing and code memory resources.

eTPU also provides a **Coherent Dual-parameter Controller - CDC** - mechanism. It is used by Host to coherently transfer pairs of parameters from/to a parameter buffer located on SDM to/from the locations on SDM where parameters are accessed directly by the channels. Coherency is guaranteed by SDM access arbitration. Although limited to two parameters only, it has lower latency and wastes no microengine resources<sup>16</sup>. CDC usage is described in [Coherent Dual-parameter Controller \(CDC\)](#).

For parameters shared by both Engines, eTPU provides **Hardware Semaphores**. Coherency is assured given the semaphores are used to prevent concurrent access to the changing parameters. Microengine can request semaphores using specific microinstructions (see [Semaphore Operations](#)). Hardware Semaphores are described in detail in [Hardware Semaphores](#).

Neither Host nor CDC have access to the hardware semaphores, but they can be combined with microcode transfer mechanisms if Host must coherently access parameters which are also shared by both Engines.

In order to ensure coherent access to a group of parameters by two or more contenders, **each contender must have atomic access** to the shared parameters. Atomicity conditions are discussed in [Host side atomic access](#) and [Microengine Side Atomic Accesses](#).

### 35.15.4.1 Host side atomic access

Host side atomic accesses can be achieved by either of following ways:

- For one parameter, the SDM should be accessed by 32-bit-wide data transfers to ensure coherency

---

16. A microengine access to the SDM in the moment CDC is performing the transfer may suffer a maximum of two wait-states.

- For two parameters only, using the Coherent Dual Parameter Controller.
- Indirectly, for any number of parameters, by requesting microcode to coherently access SDM in its behalf. The host side atomicity problem becomes, then, a microengine side atomicity problem. Some methods that use this approach to achieve coherency are described in [Multiple parameter coherency methods](#).

## 35.15.4.2 Microengine Side Atomic Accesses

### 35.15.4.2.1 Microengine Single Parameter Atomicity

SDM should be accessed by 32-bit-wide data transfers to ensure atomicity for 32-bit parameters. This applies either to Host-Microengine coherency or Microengine-Microengine coherency in a dual eTPU Engine system.

### 35.15.4.2.2 Microengine Dual Parameter Atomicity

Microengine has the ability to access two parameters coherently in back-to-back accesses, at random addresses: once it accesses SDM, it has priority over Host for another access in the next microcycle (see [SDM arbitration](#)). Note that it applies **only to Microengine-Host** coherency. For Microengine-Microengine coherency in a dual eTPU Engine system, one must use Hardware Semaphores (see [Hardware Semaphores](#)).

Microengine dual back-to-back accesses are guaranteed to be atomic in relation to Host slave accesses or Coherent Dual-parameter Controller, regardless of semaphore usage: Host or CDC accesses cannot break-up a back-to-back Microengine access, neither Microengine can break a CDC transfer, due to the SDM arbitration mechanism described in [SDM arbitration](#).

Atomicity is not guaranteed if microengine enters halt state in the middle of a back-to-back access (see [Microengine Halt State](#)): Host can access SDM while microengine is halted in the middle of a back-to-back access.

### 35.15.4.2.3 Microengine Side Multiple Atomicity

Hardware Semaphores must be used for Microengine-Microengine coherency (more than 1 parameter) since two or more accesses from one Microengine are not atomic with respect to the other.

For multiple Microengine-Host coherency, the software methods described in [Multiple parameter coherency methods](#), or similar ones, must be used. Some of these methods rely on the fact that parameter access of a thread is atomic in relation to another thread in the same Engine, since a thread cannot be suspended (preempted).

For 1 parameter coherent access, or dual parameter coherency between only one Microengine and Host, the alternatives shown in previous sections apply.

### 35.15.4.3 Coherent Dual-parameter Controller (CDC)

Dual-parameter coherency is supported by a Coherent Dual-parameter Controller hardware (CDC), which contends with microengine for SDM access. CDC atomically transfers, upon Host's command, two parameters from one area of the SDM to another. One area is a temporary (buffer) area, where the two parameters are directly read or written by the Host. This temporary area has to begin in an SDM address multiple of 2 words, and the two parameters must be sequential. The other area is the channel parameter area where the microcode normally accesses the parameters, usually with the channel relative address mode (see [SDM Addressing Modes](#)). In this area, the parameters transferred by CDC don't have to be sequential. A transfer from the temporary area to the channel area, when the Host sends data to the channel, is called a **write transfer**. Inversely, in a **read transfer** the parameters are copied from the channel area to the temporary area (channel to Host).

Coherency is guaranteed by the SDM access contention rules implemented in the SDM arbiter (see [SDM arbitration](#)). CDC transfers are coherent in respect to the two Engines, so the target parameters in the channel area may be shared by channels on them both. During CDC operation, the Host may suffer from 3 up to 11 eTPU clocks wait states<sup>17</sup>, and the Microengine(s) may suffer up to 2 microcycle wait-states<sup>18</sup>. CDC accesses are atomic with respect to Microengine(s) accesses to the SDM. Even when neither engine is in TST, CDC may suffer up to 4 eTPU clock internal wait-states from SDM arbiter, meaning 9 slave wait-states to Host, so that it does not break atomic back-to-back accesses from microengine(s). CDC also cannot break TST preload accesses. Host can initiate CDC back-to-back transfers: there is no need of idle slave cycles between two transfers.

17. The maximum number of Host wait states on CDC occurs when both microengines overlap their TSTs, delayed 3 eTPU clocks from each other.

18. One microcycle takes two eTPU clocks. Microengines get wait-states in multiples of microcycles, while Host and CDC wait-states are multiples of eTPU clocks.

## Note

SDM memory error detection and correction does not affect the number of wait-states to host due to CDC (see [Memory error support](#)).

CDC can be used to atomically fix SDM soft errors. For more details, see [Error fixing](#).

### 35.15.4.3.1 CDC programming

The Coherent Dual-parameter Controller Register (see [eTPU Coherent Dual-Parameter Controller Register \(eTPU\\_SCR\\_CDCR\)](#)) is used to configure and initiate CDC transfers between the temporary area and channel parameter area. Host asserts STS bit in order to start the data transfer. CDC then contends for the SDM and starts the transfer. When the data transfer is complete, STS returns to 0. Host receives wait-states for writing STS=1 while CDC contends for SDM and during the transfer. The write access ends when CDC finishes the transfer. Host receives wait-states during the CDC transfer. If Host writes [eTPU Coherent Dual-Parameter Controller Register \(eTPU\\_SCR\\_CDCR\)](#) with STS=0 or does not write the STS byte, the CDC transfer does not occur. CDC programming can be summarized as follows:

1. If it is a write transfer, i.e., from Host to channel, write the two parameters into temporary area.
2. Write **STS** =1 and the remaining CDC programming parameters: parameter width (32 or 24 bits, field PWIDTH), transfer direction (read or write, field WR), temporary parameter area base address (field PBBASE), and the absolute addresses of the parameters to be transferred (concatenation of the fields CTBASE and PARM0/1).
3. If it is a read transfer -- that is, from channel to host -- read the two parameters from the temporary area into Host memory/registers.

### 35.15.4.4 Hardware Semaphores

eTPU provides Hardware Semaphores accessible by the Microengine only. It is the responsibility of the application to ensure proper use of the semaphores (i.e., agree upon a specific semaphore and use it properly, to ensure coherency).

The eTPU microinstruction set has support for locking and freeing the semaphores, described in [Semaphore Operations](#), and this is the only way to access them.

There are four semaphores available, which reduces the amount of collisions by assigning unrelated data transfers to different semaphores. Semaphores are used for parameters which can be shared by channels in different Engines, and for Engine-to-Engine synchronization. Semaphores are also the only way to ensure coherent access to parameters shared between the two Microengines.

Attempting to lock one semaphore (even not successfully) frees the other locked by the same Engine, ensuring one can lock just one semaphore at a time. That prevents deadlock conditions between the two Engines.

Microcode END command or Engine being in idle state (no thread executing) automatically releases all semaphores from one Engine side, even if a semaphore lock is done in parallel. However, it is recommended to write the microcode in a way which locks semaphores for the shortest required period, and frees them without waiting for the END command, to improve the performance of the other microengine. Semaphores are free after reset. An Engine can only free a semaphore locked by itself.

Semaphore lock requests are always **non-blocking**, in the sense that they do not suspend the requester in case the semaphore is already locked. The semaphore status after the lock request - indicating if it was successfully locked or not - must be tested through the SMLCK microengine branch condition (see [Branch conditions](#)).

### **35.15.4.5 SDM arbitration**

Up to four entities can access SDM:

- Two Microengines (in a dual eTPU Engine system)
- The Coherent Dual-parameter Controller (CDC)
- The Host CPU (direct memory-mapped access)

The following rules specify the access priorities for contended access. They keep compatibility with the TPU3 dual parameter access atomicity, but only between the microengine and CDC (not Host accesses through slave bus).

1. Microengine accesses from the two eTPU Engines are interleaved between each other, but not with Host or CDC accesses;
2. The eTPU microengine(s) gives priority for SDM accesses to either the Host CPU or the CDC under any of the following conditions:
  - a. The microengine has completed accessing the second parameter in a back-to-back SDM access<sup>19</sup>.

- b. The SDM was not accessed during the last arbitration slot for the microengine and the host does not lose the access to the other engine in the current arbitration slot<sup>20</sup>
  - c. CDC is transferring data, after its first (read) access. Note that the CDC can be in middle of a data transfer of another pair of parameters, unrelated to the ones that microengine tries to access.
3. The eTPU microengine takes priority for SDM accesses under either of the following conditions:
- a. the Host CPU or CDC has done a data transfer during the last access arbitration slot for the engine<sup>20</sup>. Also, the Host CPU does not hold a pending access against the other eTPU microengine.
  - b. the microengine is arbitrating for the access of its second parameter in a back-to-back access<sup>19</sup>. All pairs of back-to-back parameter accesses are coherent with respect to Host and CDC (not to the other microengine).

The direction (read or write) of any individual access by Host or microengine is irrelevant to the arbitration. The use of Normal or PSE SDM area by the Host is also irrelevant to the arbitration.

The first parameter preloading in a TST is considered first access by the arbiter, regardless of any access made at the END microinstruction of the previous thread, that is, the last access of a thread and the first preload are never considered a back-to-back access. On the other hand, the TST preload accesses are considered back-to-back and are, therefore, atomic with respect to Host or CDC.

### Note

The Zero SDM operation (see [Zero SDM Operation](#)) is considered an SDM access for arbitration purposes both on writes and reads; the fact that read SDM data is discarded is irrelevant for arbitration.

19. If microengine tries to access the SDM in the following microcycles, the third and fourth consecutive accesses are considered the first and second of a new back-to-back dual access.

20. The microengine access slot is between its own T4 and T2 edges (see [Microcycle and I/O timing](#)).

## 35.15.5 Enhanced Channels

Enhanced Channels comprise hardware support for input digital signal processing and output signal generation. Each Channel is associated with one input and one output signal. Enhanced Channel logic is combined with Function microcode (and optionally Angle Mode logic) to implement Channel I/O functionality.

eTPU's Enhanced Channels are capable of **dual action**, meaning that each channel logic can handle two events at different times and/or cause two separated actions - these actions and events can be mutually dependent (with the first either blocking or enabling the other), or both independent, depending on the programmed **Channel Mode**.

Each Enhanced Channel contains event logic containing two **Event Register sets**, each set supporting one input and/or output action, the pair implementing dual action support. Each Event Register set contains two 24 bit registers: Match and Capture. The **Match register** holds the pending match value which is compared against one of the two time bases by an equal-only/greater-equal comparator. The **Capture register** captures one of the two time bases as a result of a Match or Transition detection. Service Requests are issued on particular combination of match and capture events, defined by the selected Channel Mode.

In the context of the eTPU channels, a **Match** is a comparison between a time base value and a channel Match register. If those two values are coincident, or the time base value is greater than the value of the Match register, a **Match Event occurs**. Depending on the channel mode of operation and current state of the channel logic, the match event may be recognized, i.e., change the state of the channel, or be ignored. A match event recognized by the channel logic is called a **Match Recognition**. Match Recognitions can cause, also depending on Channel Mode and current state, the channel to request service, configuring a **Match Service Request**.

eTPU uses two kinds of comparator to assert a Match Event: an **Equal comparator**, in which both the Match Register and the value of the selected time base must match exactly, and a **Greater-Equal comparator**. The Greater-Equal comparator considers any time base value between the range  $[N : N+0x800000-1]$  as a valid match against the value of N in the Match Register, even when the value  $N+0x800000-1$  wraps around the point of origin (0x0). See the following figure for an illustration of the matching values on a Greater-Equal comparator.

The second source of events for the eTPU channel is a **Transition** detected at the corresponding channel's input signal. Two distinct Transition detections can be programmed individually for each channel, allowing recognition of all possible combinations of edge detection. It is also possible to check the sampled state of an input

signal upon the occurrence of a Match: the sampling of the expected value is treated as a Transition, even if the input signal did not necessarily toggled at the time of the Match, or at any time at all.

Like Match Events, **Transitions Events** may or not be recognized by the channel logic. When they are, a **Transition Detection** occurs. As well as Match Recognitions, Transition Detections can issue a Channel Service Request, depending on Channel Mode and current state.

Transition Detections and Match Recognitions are sometimes simply called Transitions and Matches throughout this document, for short.

Input and output signals can be processed separately by the channel logic and microcode, and can also be combined such that Matches and Transitions are used to cause **output signal actions**. The output signals can also be directly controlled by microcode. Many event combinations are allowed for a channel, given the possibility of configuring pairs of matches and transitions for the dual action logic, where each event is able to block or enable the next one. There is a full set of Channel Modes described in [Channel Modes](#), exploring all the capabilities mentioned here.

Each channel has its own set of registers and flags. They are selected, and made accessible to the Microengine, according to the value written into the microengine **CHAN Register** that points to the desired channel. Every time the CHAN register is written, even if with the same previous value, a channel is selected and its flags and registers are updated. For further detail, see the Channel Selection Register-CHAN topic in the General Channel Registers section.

**Figure 35-303. Greater-Equal Comparator**

Beyond the request of services due to the signal and timing internal to each channel, one eTPU channel microcode can explicitly request service from another channel through the microengine **LINK Register**. A microcode write to the LINK Register asserts a service request to the channel whose number matches the contents of LINK. See [Channel Link](#) for a complete description of this mechanism.

These service requests originated in the eTPU Enhanced Channels (either time base match, input signal transition, or link service request) result in a call to the corresponding channel service routine, which is the sequence of microinstructions that is called a **Thread**. For further detail, see [Functions and threads](#).

In addition to Event Logic, each Channel has an Output Buffer Enable signal, controlled by microcode, and an Enhanced Digital Filter, which eliminates spurious glitches on input pin signal. See the chip-specific eTPU information for how the Output Buffer Enable signal is controlled.

A high level diagram of Channel logic and registers is shown in the following figure.

Figure 35-304. Channel logic block diagram

### 35.15.5.1 Channel registers and flags

Channel configuration and control registers can be divided in the following groups:

- **Host Configuration and Control registers**, which define channel Function and parameter allocation in SDM, input signal filtering, manage Host interrupts, and are used for Host Service Requests; they can only be accessed by Host, except for the Function Mode bits which can be also tested by microcode.
- **Event Registers**, which can only be accessed by eTPU Microengine, through dedicated Channel Control microinstruction operations (see [Channel Control and Configuration Microoperations](#)); these registers are directly used to implement channel functionality, and include channel event status latches which can be directly tested by Microengine branch instructions.
- **Pin Control registers**, which basically define pin state and transition polarity (but not input signal filtering); they are accessible only by dedicated Channel Control microinstruction operations.
- **Link registers**, which implement the channel link mechanism that allows one channel to request service to another one; they are accessible only by microinstruction operations.
- **General Channel registers**: CHAN, SRI, Flag0/1, PDCM, UDCM.

Most of those registers are channel exclusive, i.e., there is one copy of them for each channel. Microcode can access registers from only one channel at a time. The Channel Selection (CHAN) register (see [Channel Selection Register - CHAN](#)), accessible only by microcode, defines the channel whose registers are being accessed, with exception of link register and function mode. CHAN register assumes the value of the channel to be serviced at the beginning of TST.

The Service Request Inhibit - SRI - register controls the generation of Service Requests on matches and transitions, also affecting channel logic behavior. For a full description see [SRI - Match/Transition Service Request Inhibit Latch](#). Flag0/1 are used to select channel service threads based on channel software state. See [Flag1,Flag0 - Channel "state resolution" flags](#) for more details.

Host Configuration and Control registers are described in [Channel Configuration Control memory map and registers](#).

Time Base configuration is common to all channels, and described in [Time bases](#). Time Base selection for matches and captures, however, is individual to each channel, and is part of the Event Registers.

Link registers are described in [Channel Link](#).

The following sections describe the Event Registers and Pin Control registers.

### 35.15.5.1.1 ER - Event Registers

Each channel contains two identical Event Register sets, named ERA and ERB, corresponding to the two actions supported. Each Event Register set contains:

- a 24-bit Match register (Match A or Match B), which holds a match value. This value is compared against the selected match time base (TCR1 or TCR2).
- a 24-bit Capture register (CaptureA or CaptureB), which samples the selected capture time base (TCR1 or TCR2)
- a Time Base Selection register (TBSA or TBSB)
- a Match Recognition status flag (or latch) (MRLA or MRLB)
- a Match Recognition Enable latch (MRLEA or MRLEB)
- a Transition Detection flag (or latch) (TDLA or TDLB)
- a Transition Continuous Capture enable (TCCEA only)

ERA and ERB are associated with the first and second events in double action modes, not necessarily in that order. The order of Match events associated with ERA and ERB depends on the programmed channel mode, the MatchA and MatchB values, and the timebases selected by TBSA and TBSB. Similarly, the order of Transition events associated with ERA and ERB depends on the programmed channel mode, and the transition detection selected by IPACA and IPACB.

These registers are directly or indirectly accessed by the microcode. TBSA and TBSB registers are defined in [TBSA and TBSB - Time Base Selection Registers](#). The other registers are explained in [Match Recognition](#) and [Transition detection and Time Base Capture](#).

Access to the Event Registers is qualified by the channel currently selected by the microengine (i.e., the channel value currently in the CHAN register). During the channel transition period (automatic CHAN assignment), or whenever CHAN is written by microcode, Capture values of the new selected channel are sampled into Microengine registers ERTA and ERTB, therefore becoming visible to the microcode. At the same time, updated values of MRLA, MRLB, TDLA and TDLB are sampled into the branch logic, making the register values and the flags coherent with respect to each other and with the thread selected by the Scheduler. <sup>21</sup>

---

21. The thread selected is determined by the Entry Point which, in turn, is determined partially by the channel latches. See [Entry Point address generation](#).

## Note

The Function Mode bits are also sampled from the Host interface on Time Slot Transition, so that they remain constant to microengine even when Host changes them.

During service, the microcode can access updated values of the Event Registers of any channel by writing the channel number to CHAN. Writing CHAN with the same value (CHAN := CHAN) updates ERTA and ERTB with the new captured values, the branch logic with updated MRLA/B and TDLA/B flags. Writing CHAN with a different value does the same with the values from the newly selected channel.

Match values are also accessed through ERTA and ERTB Microengine registers, which are copied to/from the channel MatchA and MatchB registers by specific microinstruction operations.

Microcode writes to the flags and selections (MRLA/B, TDLA/B and TBSA/B) are immediately effective to the channel. The MRLA/B and TDLA/B branch conditions are also immediately reset when their correspondent flags are reset by microcode. Match registers are indirectly written by microcode through ERTA/B. MRLEA/B is unconditionally asserted when respective Match register is updated from ERTA/B, and its negation is immediate.

The following table summarizes Event Registers accesses.

**Table 35-338. Event Registers microcode accesses**

| Register           | Access type                                                                           | Sampled from channel         | Update to channel        | Microcode fields <sup>1</sup>    | Reset value <sup>2</sup> |
|--------------------|---------------------------------------------------------------------------------------|------------------------------|--------------------------|----------------------------------|--------------------------|
| CaptureA, CaptureB | read through ERTA/B                                                                   | to ERTA/B on CHAN assignment | no                       | T2ABD                            | n.a.                     |
| MatchA, MatchB     | read and write through ERTA/B                                                         | to ERTA/B by microcode       | from ERTA/B by microcode | ERWA, CMW, ERWB, T4ABS           | n.a.                     |
| MRLEA, MRLEB       | write to 0 (negate) directly;<br>write to 1 (assert) upon MatchA/B update from ERTA/B | no                           | immediate                | MRLE, ERWA, ERWB                 | 0, 0                     |
| TBSA, TBSB         | write only                                                                            | no                           | immediate                | TBSA, TBSB                       | 000, 000                 |
| MRLA, MRLB         | flag test on branch,<br>write to 0 (negate) only                                      | on CHAN assignment           | immediate                | BCC (test)<br>MRLA, MRLB (reset) | 0, 0                     |
| TDLA, TDLB         | flag test on branch,<br>write to 0 (negate) only                                      | on CHAN assignment           | immediate                | BCC (test)<br>TDL (reset)        | 0, 0                     |
| TCCEA              | write only                                                                            | no                           | immediate                | MTD                              | 0                        |

1. See [Microinstruction Set](#).
2. n.a. means that value of the register is undetermined after reset.

### 35.15.5.1.1.1 MatchA and MatchB Registers

MatchA and MatchB registers hold a match value to be compared against the selected channel time base. A match value can only be written into the Match register by microcode, through ERTA/B microengine registers (see [Write Channel Match and UDCM Registers](#)). Microcode can also read the Match register as a special T4ABS source operation, when T4ABS=0101, and the source for T4ABS is selected from the second register set. In this operation, MatchA/B registers are copied into ERTA/B registers (see [Selecting sources and destination](#)). For more information on time base matches, see [Match Recognition](#).

### 35.15.5.1.1.2 CaptureA and CaptureB Registers

CaptureA and CaptureB registers capture the selected channel time base. CaptureA/B registers cannot be directly written or read by microcode. During the Time Slot Transition (TST) or during CHAN assignment, CaptureA/B registers are copied into ERTA/B microengine registers. For more information, see [Transition detection and Time Base Capture](#).

### 35.15.5.1.1.3 TBSA and TBSB - Time Base Selection Registers

TBSA/B are 3-bit registers which have the following effect on channel configuration:

- Selection of the timebase (TCR1 or TCR2) to be compared against the match values in MatchA and/or MatchB registers.
- Selection of the timebase (TCR1 or TCR2) to be captured in the CaptureA and/or CaptureB registers by a match or transition detection event.
- Selection of comparator mode to be used with MatchA and MatchB registers: equal-only or greater-equal.

After reset TBSA/B are 000. The following table shows values of TBSA and TBSB for configuration selection. Note that the time base selection for capture is independent of the time base selected for matches.

**Table 35-339. TBSA/B Programming States**

| TBS bit   | 2                    | 1                           | 0                         |
|-----------|----------------------|-----------------------------|---------------------------|
| bit value | Comparator selection | Capture time base selection | Match time base selection |
| 0         | greater or equal     | TCR1                        | TCR1                      |
| 1         | equal-only           | TCR2                        | TCR2                      |

TBSA/B are written through the microcode fields TBSA/B (see [Comparator and Time Base Selection](#)).

#### 35.15.5.1.1.4 MRLA/B - Match Recognition Latches

See [MRLA/B - Match Recognition Latches](#).

#### 35.15.5.1.1.5 MRLEA/B - Match Recognition Latch Enable

See [MRLEA/B - Match Recognition Latch Enable](#).

#### 35.15.5.1.1.6 TDLA/B - Transition Detection Latch

See [TDLA/B - Transition Detect Latches](#).

#### 35.15.5.1.1.7 TCCEA - Transition Continuous Capture Enable

See [TCCEA - Transition Continuous Capture Enable](#).

### 35.15.5.1.2 Pin Control Registers

Pin Control Registers are replicated one per channel, accessed only by microcode and qualified by the CHAN register in the same way as Event Registers.

The following table lists Pin Control Registers, explained in following subsections, and their accesses.

**Table 35-340. Pin Control Registers microcode accesses**

| Register     | Access type                | Sampled from channel | Update to channel | Microcode fields <sup>1</sup> | Reset value |
|--------------|----------------------------|----------------------|-------------------|-------------------------------|-------------|
| IPACA, IPACB | write only                 | no                   | immediate         | IPACA, IPACB                  | 000,000     |
| OPACA, OPACB | write only                 | no                   | immediate         | OPACA, OPACB                  | 000,000     |
| PSTI         | flag test on branch        | no                   | no                | BCC                           | 0           |
| PSTO         | flag test on branch, write | no                   | immediate         | BCC (test)                    | 0           |

*Table continues on the next page...*

**Table 35-340. Pin Control Registers microcode accesses (continued)**

| Register         | Access type         | Sampled from channel | Update to channel | Microcode fields <sup>1</sup> | Reset value       |
|------------------|---------------------|----------------------|-------------------|-------------------------------|-------------------|
|                  |                     |                      |                   | PSC, PSCS (set)               |                   |
| OBE <sup>2</sup> | write only          | no                   | immediate         | TBSA values 1000,1001         | 0<br>(negated)    |
| PSS              | flag test on branch | on CHAN assignment   | no                | BCC                           | n.a. <sup>3</sup> |
| PRSS             | flag test on branch | on CHAN assignment   | no                | BCC                           | n.a. <sup>4</sup> |

1. See [Microinstruction Set](#).

2. Although this register exists for code compatibility reasons, OBE functionality is not available on this chip.

3. PSS is PSTI or PSTO sampled on CHAN assignments and at thread start.

4. PRSS is PSTI sampled on channel service request.

### 35.15.5.1.2.1 IPACA/B and OPACA/B - Input and Output Pin Action Control Registers

These registers determine the transition detections and output pin actions which takes place due to match or transition events. Each field is three bit wide. After reset, the IPACA/B and OPACA/B registers are set to 000. IPACA and IPACB registers are mutually independent and have identical encoding, and so do OPACA and OPACB. The table below shows IPAC and OPAC encoding. Note that transition detections are independent from the output actions, but some options of output actions are triggered by transition detections. Output actions can also be triggered by Matches. For a detailed definition of Transition Detections, see [Transition detection and Time Base Capture](#).

IPACA/B define the Transition events treated by channel logic. Although the name "transition" is generically used for the transition detections, IPAC options 100 and 101 do not really detect transitions: they actually sample the state of the input signal at the occurrence of the corresponding Match (Match A used for IPACA, Match B used for IPACB).

**Table 35-341. IPACA/B and OPACA/B Encoding**

| Value | IPAC meaning                                  | OPAC meaning                                 |
|-------|-----------------------------------------------|----------------------------------------------|
| 000   | Do not detect transitions                     | Do not change output signal                  |
| 001   | Detect rising edge only                       | Match <sup>1</sup> sets output signal high   |
| 010   | Detect falling edge only                      | Match <sup>1</sup> sets output signal low    |
| 011   | Detect either edge                            | Match <sup>1</sup> toggles output signal     |
| 100   | Detect input signal = 0 on Match <sup>1</sup> | Transition sets output signal low            |
| 101   | Detect input signal = 1 on Match <sup>1</sup> | Transition detection sets output signal high |
| 110   | reserved                                      | Transition detection toggles output signal   |
| 111   | n.a. <sup>2</sup>                             | n.a. <sup>2</sup>                            |

1. Match A is used for IPACA/OPACA, and Match B for IPACB/OPACB.
2. On the microinstruction fields IPACA/B and OPACA/B this value is neutral, meaning that IPAC/OPAC register values are not changed.

### 35.15.5.1.2.2 Output Pin Control Logic and Pin State Output Register - PSTO

The output signal control logic uses OPACA/B, the Pre-defined Channel Mode (PDCM) and the User Defined Channel Mode (UDCM), and the microcode Pin State Control (PSC and PSCS) fields. It is responsible for setting the Pin State Output (PSTO) register to the specified logic value required by microcode, by input events, or by Match A and/or Match B events. The PSTO register stores the driven pin state determined by the Pin Control logic. The Output Buffer Enable signal, if used at MCU integration, must be set by microcode (using TBSA field) to make the pad propagate the PSTO register output to the actual pin.

PSTO register output also goes to the microengine branch logic, enabling branching on the driven pin state. PSTO is set to 0 on reset.

The PSC and PSCS microcode fields are used for setting the PSTO register to a fixed value, or to the value specified by the OPACA or OPACB microcode field, as shown in the following table.

**Table 35-342. PSC and PSCS encoding**

| PSC | Output pin action                                              |
|-----|----------------------------------------------------------------|
| 00  | Force pin state according to OPACA (PSCS=0) or OPACB (PSCS=1). |
| 01  | Force pin high.                                                |
| 10  | Force pin low.                                                 |
| 11  | Do not change pin state.                                       |

See [Channel Control and Configuration Microoperations](#) for details.

On occurrence of match recognitions or transition detections, the pin control logic sets PSTO value according to the event number (Match A/Transition A or Match B/Transition B) and the contents of OPACA/IPACA or OPACB/IPACB registers. There are cases in which two match or transition events may occur at the same time, each of them trying to force a different pin action. The resolution of the selected match event which sets the value depends on the Pre-defined Channel Mode (PDCM) register and the User Defined Channel Mode (UDCM). For details refer to [Match/Transition Pin Action Conflict Resolution](#).

### 35.15.5.1.2.3 PSTI and PSS - Pin State Input and Pin Sampled State Registers

During the time slot transition period, or whenever the CHAN register is written by microcode, the filtered<sup>22</sup> input signal PSTI or output signal PSTO (selected by the ETPD field in [eTPU Channel n Configuration Register for Engine 1](#) (eTPU\_CCCR\_CnCR\_ENG1) and [eTPU Channel n Configuration Register for Engine 2](#) (eTPU\_CCCR\_CnCR\_ENG2)) is sampled into the branch logic as the PSS flag (see [Table 35-411](#)). The microcode can then branch on either the currently driven (PSTO) or input (PSTI) pin state, or on sampled pin state (PSS, which is stable as long as CHAN does not change).

#### Note

If a transition occurs simultaneously (after the filter) with the CHAN assignment, PSS samples the new pin value. Therefore, if TDLA/B is cleared simultaneously with the assignment CHAN := CHAN, the occurrence of a transition at this very moment can still be tested with PSS.

### 35.15.5.1.2.4 PRSS - Pin Request Service Sample

Channel logic can, depending on its state and programmed mode, request service to the eTPU microengine (see [Functions and threads](#)). When the channel logic issues a service request, the filtered input signal PSTI is sampled into an internal channel flag PRSS. There is one such PRSS flag for each channel (see [Pin Control Registers](#)). Channel PRSS keeps its value until all its service request sources are cleared and until a new channel service request rises.

#### NOTE

Only channel service requests update PRSS. It is not updated by host service requests (HSRs) or by link service requests. Moreover, a channel service request updates PRSS even if the channel is disabled (its CPR set to 0, see [eTPU Channel n Configuration Register for Engine 1](#) (eTPU\_CCCR\_CnCR\_ENG1) and [eTPU Channel n Configuration Register for Engine 2](#) (eTPU\_CCCR\_CnCR\_ENG2)).

The channel PRSS flag is sampled into the branch logic as the PRSS flag (see [Table 35-411](#)) during the time slot transition period, or whenever the CHAN register is written by microcode.

22. The filter can be bypassed.

35.15.5.1.2.5 OBE - Output Buffer Enable control latch

NOTE

Output Buffer Enable is not available on this chip.

OBE latch drives the Output Buffer Enable signal, which can be used to control the output signal pad driver. Channel output comes disabled from reset. If an Output Buffer Enable signal<sup>23</sup> from eTPU is used on MCU integration and a signal is desired to be output in a channel, OBE signal must be set by microcode. Microcode field TBSA is used to set/reset the Output Buffer Enable control when microcode field TBSA bit 3 is 1, according to the following table.

Table 35-343. TBSA Output Buffer control

| microcode<br>TBSA[2:0] | meaning when TBSA[3]=1 |
|------------------------|------------------------|
| 000                    | enable output buffer   |
| 001                    | disable output buffer  |
| 111                    | do nothing             |
| other values           | reserved               |

23. There is one independent OBE signal for each channel.

### 35.15.5.1.3 General Channel registers

These registers control other aspects of channel logic. Except for CHAN, they are unique per channel. The following table summarizes the registers and access options.

### Table 35-344. General Channel registers microcode access

| Register | Access type | Sampled from channel | Update to channel | Microcode fields <sup>1</sup> | Reset value                                  |
|----------|-------------|----------------------|-------------------|-------------------------------|----------------------------------------------|
| CHAN     | read/write  | n.a. <sup>2</sup>    | n.a. <sup>2</sup> | T4ABS, T4BBS, T2ABD           | defaults to serviced channel at thread start |
| PDCM     | write only  | no                   | immediate         | PDCM                          | 1100                                         |

*Table continues on the next page...*

**Table 35-344. General Channel registers microcode access (continued)**

| Register     | Access type             | Sampled from channel | Update to channel      | Microcode fields <sup>1</sup> | Reset value                            |
|--------------|-------------------------|----------------------|------------------------|-------------------------------|----------------------------------------|
|              |                         |                      |                        |                               | (sm_st)                                |
| UDCM         | write only              | no                   | from ERTA by microcode | CMW, ERWA                     | parameter value defined at integration |
| SRI          | write only              | no                   | immediate              | MTD                           | 1                                      |
| Flag1, Flag0 | branch flag test, write | no                   | immediate              | BCC, FLC                      | 0, 0                                   |

1. See [Microinstruction Set](#).

2. CHAN is common to all channels in the Engine.

### 35.15.5.1.3.1 Channel Selection Register - CHAN

CHAN is the register that holds the number of the channel that qualifies the context of most Channel Registers, including Pin Control and ER accesses, and is common to all channels in a same Engine.

When a thread starts to be executed, the contents of CHAN register is automatically updated on Time Slot transition to the number of the channel to be serviced. Serviced channel is constant during channel servicing, but the selected channel can be changed any time by microengine writing into CHAN register.

Some microinstructions are affected by the serviced channel instead of CHAN. These are:

- Conditional branch using LSR (see [LINK Register](#)) or Function Mode (see [eTPU Channel n Status Control Register for Engine 1 \(eTPU\\_CCCR\\_CnSCR\\_ENG1\)](#) and [eTPU Channel n Status Control Register for Engine 2 \(eTPU\\_CCCR\\_CnSCR\\_ENG2\)](#)).
- Negate channel flag LSR, Interrupt CPU and Data Transfer Request (see [Channel Interrupt and Data Transfer Requests](#)).

When CHAN register is written, accesses are qualified by the new CHAN register value from the instruction following CHAN assignment on, except CaptureA/B sampling into ERTA/B and Match register writing from ERTA/B (see [CHAN assignment, Read Match and ERWA/B](#)).

Writing CHAN (including with the same value, CHAN:= CHAN) updates ERTA and ERTB with the new captured values, the branch logic with updated MRLA/B and TDLA/B flags.

The following table shows the commands, flags and registers selected by the CHAN register value.

**Table 35-345. CHAN-selected features**

| Feature used                                                                                               | Selected by CHAN |
|------------------------------------------------------------------------------------------------------------|------------------|
| Channel-relative SDM access                                                                                | YES              |
| Branch using PSS, PRSS, PSTI and PSTO channel flags                                                        | YES              |
| Branch using MRLA/B, TDLA/B, Flag0/1 <sup>1</sup>                                                          | YES              |
| Branch on all other conditions <sup>2</sup>                                                                | no               |
| ERTA/B Value                                                                                               | YES              |
| Configure (selected) channel                                                                               | YES              |
| Channel commands applied to: MRLA/B, TDLA/B, TBSA/B, IPACA/B, OPACA/B, PSC, PSCS, OBE, PDCM, MRLE, Flag0/1 | YES              |
| Channel command: set/reset SRI                                                                             | YES              |
| Channel command: write to Match registers (ERWA/B)                                                         | YES <sup>3</sup> |
| Channel command: read Match registers into ERTA/B                                                          | YES              |
| Clear LSR                                                                                                  | no               |
| Channel interrupts and data transfer requests (CIRC)                                                       | optionally       |

1. In TPU, these conditions retained the old values.
2. See [Branch Operations](#)
3. If write Match (ERWA/B) occurs at the same time of a CHAN assignment, the channel which is target of the write is the one selected by the new CHAN value. See [CHAN assignment](#), [Read Match](#) and [ERWA/B](#).

### 35.15.5.1.3.2 PDCM - Predefined Channel Mode

PDCM determines the channel mode assigned to the channel. Channel mode defines much of the channel logic behavior, specially how matches blocks and enables transitions and vice-versa, as well as occurrence of time base captures and service requests based on matches and transitions. For a complete description see [Channel Modes](#).

PDCM is a 4-bit register set by the microcode field of the same name (see [Predefined Channel Modes](#)), and cannot be read or tested in branch instructions. The table below relates the PDCM value with channel modes. The second column specifies the mnemonic used to reference the mode, introduced in [Channel Modes Overview](#). There is one PDCM for each channel, initialized with 1100 on reset.

PDCM is also used to select the User Programmable Channel Mode. If this selection is made, the channel behavior is defined by the settings of the UDCM register (see [UDCM - User Defined Channel Mode](#)).

**Table 35-346. PDCM encoding**

| PDCM | Channel mode |
|------|--------------|
| 0000 | em_b_st      |
| 0001 | em_b_dt      |
| 0010 | em_nb_st     |

*Table continues on the next page...*

**Table 35-346. PDCM encoding (continued)**

| PDCM | Channel mode              |
|------|---------------------------|
| 0011 | em_nb_dt                  |
| 0100 | m2_st                     |
| 0101 | m2_dt                     |
| 0110 | bm_st                     |
| 0111 | bm_dt                     |
| 1000 | m2_o_st                   |
| 1001 | m2_o_dt                   |
| 1010 | User Defined Channel Mode |
| 1011 | reserved                  |
| 1100 | sm_st <sup>1</sup>        |
| 1101 | sm_dt                     |
| 1110 | sm_st_e                   |
| 1111 | n.a. <sup>2</sup>         |

1. This is the reset value, also compatible with TPU channel behavior.

2. This value is used as a neutral (do not change) value in the PDCM microinstruction field.

### 35.15.5.1.3.3 UDCM - User Defined Channel Mode

UDCM holds the control signals that define the channel logic behavior in terms of Match and Transition blocking and enabling, captures and service requests triggered by events. The register layout is defined in the figure below. The individual fields are defined in [Channel Mode Logic and Event Flags](#). There is one UDCM register for each channel, which can be independently programmed.

UDCM can only be written into the Match register by microcode, through ERTA/B microengine registers (see [Write Channel Match and UDCM Registers](#)).

|     |      |      |       |       |       |      |       |       |      |       |     |      |   |
|-----|------|------|-------|-------|-------|------|-------|-------|------|-------|-----|------|---|
| 13  | 12   | 11   | 10    | 9     | 8     | 7    | 6     | 5     | 4    | 3     | 2   | 1    | 0 |
| MSR | MCAP | M1ET | M1EM2 | M1BM2 | M2BM1 | M2BT | T1BM1 | T2BM1 | TBM2 | T1ET2 | TSR | TCAP |   |

**Figure 35-306. UDCM Register**

### 35.15.5.1.3.4 SRI - Match/Transition Service Request Inhibit Latch

SRI blocks channel service requests due to the assertion of MRLA/B and/or TDLA/B. SRI does not affect recognition of Link Service Requests or Host Service Requests, neither MRLA/B or TDLA/B microcode branch tests nor Entry Table selection<sup>24</sup>. SRI is asserted during reset and is controlled by microcode field MTD.

24. In TPU, SRI also blocked TDL and MDL branches and enabled any transition to capture time base.

To unburden the microengine, SRI asserted configures a channel "dumb" regarding the servicing of match and capture channel service requests. Even with SRI=1, TDLA/B and MRLA/B can still be asserted, and the level specified by the OPAC (Output Pin Action Control) registers will be output to the pin.

### 35.15.5.1.3.5 Flag1,Flag0 - Channel "state resolution" flags

Each channel has a pair of flags, simply called Flag0 and Flag1, that can be set/reset by microcode through microinstruction field FLC. FLC sets/resets Flag0/1 of the channel selected by CHAN. These flags can be tested by microcode, and are also used to resolve the microcode entry point for the channel service (see [Entry Points](#)). Flag0 and Flag1 are, so, typically used for fast state resolution. FLC microinstruction field also allows Flag1,Flag0 to be copied from selected bits of P register high byte, which is also meant to be used to hold application state. Flag0 and Flag1 are both zero out of reset.

## 35.15.5.2 Match Recognition

The match operation is performed every microcycle by comparing the channel MatchA and MatchB registers against the value of the TCR bus specified for each match. TCR1 or TCR2 bus is selected according to TBSA and TBSB fields. Both results have effect on the next clock cycle (see [Microcycle and I/O timing](#)).

A Match A/B event is qualified by a set of match enabling conditions to the Match Recognition Registers MRLA/B. To recognize the match, the following match enabling conditions are required:

- For IPACA/B=0xx, Match Enable Flag (MEF), qualified by the channel currently being serviced must be asserted. For IPACA/B =1xx, Match A/B is always enabled (even during Time Slot Transition - TST), regardless the state of the Match Enable Flag (MEF). See [MEF - Match Enable Flag](#) for the conditions of MEF assertion.
- Match Recognition Latch Enable 1/2 (MRLEA/B) is asserted. A match event recognition may only occur if its corresponding MRLEA/B bit is set, which only happens upon a write to a channel match register by the microcode, copied from ERTA/B. MRLEA/B is negated when the respective match occurs or, in some double match channel modes, when a match for the other Match register occurs. It ensures that the greater-equal comparison will not cause additional matches<sup>25</sup>.
- In selected modes (see [Channel Modes](#)), the particular conditions of MRL and TDL flags of the other event, i.e:

---

25. Microcode can also negate MRLEA/B.

- MRLA, TDLA enable or block MRLB;
- MRLB, TDLB enable or block MRLA.
- The respective MRL is negated.
- In selected modes (see [Channel Modes](#)), the state of its respective TDL flag.

If the Match A and/or Match B conditions are met, the channel immediately forces the pin state if specified by the appropriate OPACA/B registers (Output Pin Action Control 1/2) and, in some cases, by IPACA/B registers. Refer to [IPACA/B and OPACA/B - Input and Output Pin Action Control Registers](#).

If both Match A and Match B events occur at the same time, with conflicting pin actions, the priority over the pin action is mode dependent. For further details on pin action resolution refer to [Match/Transition Pin Action Conflict Resolution](#).

#### 35.15.5.2.1 MRLA/B - Match Recognition Latches

MRLA/B indicate the recognition of a match event detected by the comparator. They can be asserted either on T2 or T4 (see [Microcycle and I/O timing](#)). Assertion of MRLA/B issues a match Service Request in specific channel modes, depending on previous events and state of SRI. After reset MRLA and MRLB are both negated.

When MRLA or MRLB is asserted, it may change the output signal level according to the Input and Output Pin Action Control registers (refer to [IPACA/B and OPACA/B - Input and Output Pin Action Control Registers](#)). Assertion of MRLA/B causes a capture of one or two time bases, according to the selected mode capturing scheme (see [Transition detection and Time Base Capture](#))

A match recognition is self-blocking, regardless of Channel Mode: once MRLA (MRLB) has been asserted, it negates its associated MRLEA (MRLEB) register, preventing future match recognitions, until the associated match register is rewritten by microcode. The microcode has to enable new matches by updating the new match value in the MatchA (MatchB) register<sup>26</sup>. In addition, assertion of MRLA/B can block its twin MRLB/A, depending on the channel mode. In some double match blocking channel modes, Match A/B event blocks the occurrence of Match B/A in a "first win" scheme.

It is the transition from 0 to 1 in MRL that causes the Match actions, except the service request: apart from MRLEA/B negation(s) and service request, no action due to a Match occurs if MRL was already set to 1, even if the other MRL assert conditions are satisfied. However, if a Match and a microoperation negating its corresponding MRL occur at the

26. Before that, microcode should also negate MRLA (MRLB), otherwise an old match may be recognized by the scheduler and serviced as a new one

same time, MRL negation by microcode overrides its assertion, but any dependable captures and pin action occurs anyway (if MRL was already negated before), and also the negation of MRLE(s) (the respective one and, in some channel modes, the other, regardless of MRL state before). Note that MRLE must have been set before (by writing a new Match value).

### 35.15.5.2.2 MEF - Match Enable Flag

MEF is a one-bit latch that is unique for all channels in an Engine.

MEF can selectively enable assertion of MRLA/B, depending on the IPACA/B field. For IPACA/B=0xx, MEF=1 enables assertion of MRLA/B for the scheduled channel during service. For IPACA/B=1xx, Match A/B is always enabled, regardless the state of the MEF, but it still depends on the other Match recognition conditions. Matches of channels not being serviced are never disabled by MEF.

MEF is not accessible by Microengine or Host. MEF is negated for two microcycles in the beginning of the time slot transition period. After two microcycles (plus wait-states) into TST, the ME bit in the entry point is copied to MEF to allow selective enabling of MRL for each thread (refer to [Time Slot Transition](#)). MEF is asserted unconditionally soon after a thread ends.

If a channel service needs to postpone a programmed match, MEF assures that microcode wins the race against match event after time slot transition (only for IPAC=0xx).

Note that a match event may be lost during the periods when MEF is negated only if:

- the match comparator is configured for "equal-only" behavior, and
- IPACA/B=0xx, and
- TCR increments at the rate of eTPU clock divided by 2 or faster.

When the comparator is configured as "greater-equal", the match event that occurred when MEF was negated may be recognized after MEF is asserted again, due to the "greater than" condition.

### 35.15.5.2.3 MRLEA/B - Match Recognition Latch Enable

MRLEA/B is negated upon the assertion of its respective MRLA/B. In blocking match channel modes it may also be negated together with the assertion of the twin MRLB/A. The MRLEA/B bits ensure that data captured due to the first match event will not be overwritten when MRLA/B is negated: due to greater-equal comparison, the match condition continues to be true, but should not cause another capture event.

In addition to negation by local match event, the microcode can negate both MRLEA and MRLEB, to block pending matches, and also MRLA/B, individually. This action will prevent future match events from the selected channel.

Writing the MatchA/B registers by microcode to schedule the next match values sets MRLEA and/or MRLEB and enables new matches. This setting overrides the MRLE negation conditions due to channel logic or microcode (see [Channel Modes](#)). By combining write to Match A/B with MRLEA/B negation microinstructions, the microcode can negate one MRLE while asserting the other.

### Note

If the MRLE negation conditions continue after writing MatchA/B registers, the respective MRLE does not keep asserted. For instance, if MRL=1 and a match is programmed for a time value in the past during a thread with ME=1, then MRLE will be cleared soon after MatchA/B is written, even though a match does not occur (because MRL was already asserted, neither captures nor pin toggles occur).

When the match register is updated (with MRLE already asserted before) and field MRLA/B = 1 (no clear, see [Clear Transition/Match Event Registers](#)) and MRLA/B flag is zero, the eTPU behaves exactly as the TPU, that is: a match that comes concurrently with the rewrite of the match register, matching the old value, sets the MRL, as if the setting of the MRLE due to match register write had precedence over its clear by the match at that moment. After this simultaneous operation, the MRLE value stays at 1, and the captured time base value, if any, reflects the match value.

When the match register is updated (with MRLE already asserted before) and field MRLA/B = 0 (clear MRL, see [Clear Transition/Match Event Registers](#)) and MRLA/B flag is zero, the match captures will occur, the MRLA/B flag will keep negated, and MRLE will stay asserted. Special care must be taken when a match is reprogrammed on a channel running at T2/T4 timing, please see the details in the “T2/T4 Channel Timing” section.

### 35.15.5.3 Transition detection and Time Base Capture

Time Base Capture(s) occur when the value of a specified TCR is sampled into the CaptureA and/or CaptureB register. TBSA[1] and TBSB[1] select which TCR will be captured in CaptureA and CaptureB, respectively.

A capture event may occur due to either of the following events:

- The assertion condition of Match Recognition Latch (MRL), even if MRL is simultaneously negated by microcode
- The assertion condition of Transition Detection Latch (TDL), even if TDL is simultaneously negated by microcode.
- Any Transition Event specified by IPACA if both the Transition Detection Latch TDLA and Transition Continuous Capture Enable TCCEA are asserted.

A capture event occurs together with the assertion of MRL or TDL either on T2 or T4 positive edges, and captures the time-base value that caused the match, even if TCR1/2 increments concurrently with the assertion (see [Microcycle and I/O timing](#))<sup>27</sup>. MRLA/B and TDLA may, depending on the channel mode, inhibit the capture of the second event's TCR into CaptureA/B. As a general rule, values captured by signal transitions are not overwritten by values captured by match events.

When the enable bit TCCEA is asserted, captures due to Transition Events also occur after TDLA is asserted. Those captures happen on transition events specified by IPACA, and the TCR value is saved into CaptureA register only.

The capturing scheme is defined by the Channel Mode programmed at register PDCM, or at register UDCM when User Defined Channel Mode is selected. For more information on mode-dependent capture schemes refer to [Channel Modes](#).

### 35.15.5.3.1 TDLA/B - Transition Detect Latches

TDLA/B indicate detection of specific transition occurrences on a channel input signal. TDLA and TDLB assertion causes service request in single and double transition predefined modes, respectively. TDLB assertion does not cause Service Request in single transition predefined modes, and TDLA assertion does not cause Service request in double transition predefined modes. In single transition channel predefined modes TDLB can be asserted on the second transition, but does not generate Service Request. Yet on predefined modes, TDLB assertion is enabled only if TDLA is asserted to detect an ordered input signal double transition. All the restrictions above, however, may be overridden by using the User Defined Channel Mode. The IPACA and IPACB registers indicate the programmed edges of the first and second detected transition, respectively.

The sampling of a determined value (0 or 1) on the input signal due the occurrence of a Match is also treated as a "transition", depending on IPACA/B programming (see [IPACA/B and OPACA/B - Input and Output Pin Action Control Registers](#)). When using a channel mode where the transition1 is initially blocked and IPACA is programmed to detect such "transitions", the occurrence of a Match A only unblocks the transition after

---

27. In TPU3, when TCR1 was counting at maximum rate of eTPU clock divided by 2, the next value was captured.

the sampling. It means that the transition on the first Match (IPACA configurations 100 and 101) is not effective on predefined modes where Transition A is enabled by Match A (m2\_st, m2\_dt, m2\_o\_st and m2\_o\_dt) or user-defined modes with UDCM bit M1ET asserted. A Transition A can still happen after the Match A, however, if MatchA register is reprogrammed without clearing MRLA.

TDLA/B assertion conditions initiates a capture event of one or both selected TCR buses. TDLA or TDLB transition event generates a Service Request, depending on channel mode, previous events and the state of SRI. For more information on service request scheme refer to [Entry Point address generation](#) and [Channel Modes](#).

Assertion of TDLA/B occurs on either T2 or T4 positive edges. The capture event occurs on the same clock, and captures the time base value present when TDLA/B was asserted<sup>28</sup>. TDLA and TDLB are negated during reset and may also be negated independently by microcode. TDLA/B is reset by no way other than reset and microcode.

It is the transition from 0 to 1 in TDL that causes the Transition actions: even if TDL assert conditions are satisfied, no action due to a Transition occurs if TDL was already set to 1. However, if a Transition and a microoperation negating TDLs occur at the same time and TDL was already negated, TDL negation by microcode overrides its assertion, but any dependable captures and pin action occurs anyway.

### **35.15.5.3.2 TCCEA - Transition Continuous Capture Enable**

TCCEA enables capture from transitions after the TDLA flag is set. TCCEA is negated on reset, so that a capture occurs only when TDLA asserts. TCCEA can be set and reset by microcode only, through the instruction field MTD (see [Disable Match and Transition Service Requests](#)). It can only be set together with inhibiting of the channel service requests (SRI = 1)<sup>29</sup>.

When TCCEA is asserted, the transition events specified by IPACA that occur after TDLA is set also cause captures, into the CaptureA register only. However, output actions related to transition events are still blocked by TDLA.

---

28. In TPU3, when TCR1 was counting at maximum rate of eTPU clock divided by 2, the next value was captured.

29. TCCEA provides compatibility with TPU when service request is inhibited.

### 35.15.5.4 Channel Modes

The Enhanced Channels support various modes of operation combining Match A/B recognition and transition detection events which set MRLA/B and TDLA/B. The channel mode is individually set for each channel by eTPU microcode, through the PDCM register (see [PDCM - Predefined Channel Mode](#)). The PDCM register selects among a set of 13 predefined channel modes, and also a user-defined channel mode.

The order in which events occur, combined with assigned channel mode, establish which following event detections are inhibited and/or enabled, as well as the actions taken: Time Base capture, flag setting (MRLA/B, TDLA/B), match disabling (MRLEA/B), output signal transition, and Service Request. Those channel mode characteristics are fixed in the predefined modes, but can be individually programmed in the user-defined channel mode.

A generic description of channel modes from the usage point of view can be found in [Channel Modes Overview](#). Each mode is named with a mnemonic acronym for terse reference. The individual programmed attributes of the user-programmable channel mode are also described.

The modes are used differently for input and output signals, as explained in [Predefined Channel Modes on Input Signal Processing](#) and [Channel Modes on Output Signal Generation](#). Modes also allow combining input processing and output generation in a single channel, as exemplified in [Combining Input and Output Signals](#).

[Channel Mode Logic and Event Flags](#) shows a structural definition of channel logic and its relation to channel modes. A dynamic, event-oriented view of each channel mode can be found in [Channel Mode Summary](#).

#### 35.15.5.4.1 Channel Mode Logic and Event Flags

[Figure 35-307](#) shows a more detailed diagram of channel mode logic. The logic shown here is not necessarily identical to the actual channel logic implementation, but is equivalent with respect to conditions for event blocking, enabling, capture, and service requests.

Signals MSR, TSR, MCAP, TCAP, M1ET, M1EM2, M1BM2, M2BM1, M2BT, T1BM1, T2BM1, TBM2 and T1ET2 are decoded from programmed channel mode PDCM in predefined modes, and come directly from the UDCM register when user-defined mode is selected:

- TSR (1 bit) defines Service Requests issued by Transitions, as shown in [Table 35-348](#).
- MSR (2 bits) defines Service Requests issued by Matches, as shown in [Table 35-347](#).

- TCAP (1 bit) defines time base captures caused by Transitions, as shown in [Table 35-348](#)
- MCAP (1bit) defines time base captures caused by Matches, as shown in [Table 35-349](#).
- M1ET, M1EM2, M1BM2, M2BM1, M2BT, T1BM1, T2BM1, TBM2, T1ET2 (1 bit each) define Match and Transition reciprocal blocking and enabling, as well as Transition ordering, as shown in [Table 35-350](#) and [Table 35-351](#).

[Table 35-352](#) shows the decoded values of those control signals for each predefined channel mode. The first column shows the mnemonic reference for the predefined channel modes described in the following sections.

Changing PDCM or the UDCM when user mode is selected may set or reset any of the channel flags, or issue captures and service requests, so it is advisable to switch channel modes only in a quiescent channel state, with channel flags MRLEA/B, TDLA/B, MRLA/B cleared. Furthermore, an event flag asserted in one mode may keep asserted after the mode programming change, even if the flag is impossible to be set in the new mode.

**Table 35-347. MSR signals - Match Service Requests**

| value | MSR                                             |
|-------|-------------------------------------------------|
| 00    | issue no Service Requests on Matches            |
