Reads of the SEMA4_RSTGT register return the encoded state machine value. The reset state machine is maintained in a 2-bit, 3-state implementation, defined as:<br>00 Idle, waiting for the first data pattern write.<br>01 Waiting for the second data pattern write.<br>10 The 2-write sequence has completed. Generate the specified gate reset(s). After the reset is performed, this machine returns to the idle (waiting for first data pattern write) state. Note that the RSTGSM = 0b10 state is valid for only a single machine cycle, so it is impossible for a read to return this value<br>11 This state encoding is never used and therefore reserved. |           |             |           |                 |                           |               |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |               |                           |               |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |            |               |                                                                                                                                                                                                                                                 |

This 3-bit read-only field records the logical number of the bus master performing the gate reset function. The reset function requires that the two consecutive writes to this register be initiated by the same bus master to succeed. This field is updated each time a write to this register occurs. The association between system bus master port numbers, the associated bus master device and the logical processor number is SoC-specific. See the chip configuration chapter for this information.                                                                                                                                                                 |           |             |           |                 |                           |               |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |               |                           |               |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |            |               |                                                                                                                                                                                                                                                 |

This field is updated by the second write.</p> <p>If RSTGTN &lt; 64, then reset the single gate defined by RSTGTN, else reset all the gates. The corresponding secure IRQ notification state machine(s) are also reset.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |           |             |           |                 |                           |               |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |               |                           |               |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |            |               |                                                                                                                                                                                                                                                 |

### 13.3.20 Semaphores (Secure) Reset IRQ Notification (SEMA4\_RSTNTF)

As with the case of the secure reset function and the hardware gates, it is recognized that system operation may require a reset function to re-initialize the state of the IRQ notification logic without requiring a system-level reset.

To support this special notification reset requirement, the Semaphores module implements a "secure" reset mechanism which allows an IRQ notification (or all the notifications) to be initialized by following a specific dual-write access pattern. When successful, the specified IRQ notification state machine(s) are reset. Using a technique similar to that required for the servicing of a software watchdog timer, the secure reset mechanism requires two consecutive writes with predefined data patterns from the same processor to force the clearing of the IRQ notification(s). The required access pattern is:

1. A processor performs a 16-bit write to the SEMA4\_RSTNTF memory location. The most significant byte (SEMA4\_RSTNTF[RSTNDP]) must be 0x47; the least significant byte is a "don't\_care" for this reference.
2. The same processor then performs a second 16-bit write to the SEMA4\_RSTNTF location. For this write, the upper byte (SEMA4\_RSTNTF[RSTNDP]) is the logical complement of the first data pattern (0xB8) and the lower byte (SEMA4\_RSTNTF[RSTNTN]) specifies the notification(s) to be reset. This field can specify a single notification be cleared, or that all notifications are cleared.
3. Reads of the SEMA4\_RSTNTF location return information on the 2-bit state machine (SEMA4\_RSTNTF[RSTNSM]) which implements this function, the bus master performing the reset (SEMA4\_RSTNTF[RSTNMS]) and the notification number(s) last cleared (SEMA4\_RSTNTF[RSTNTN]). Reads of the SEMA4\_RSTNTF register do not affect the secure reset finite state machine in any manner.

Address: 0h base + 104h offset = 104h

|                |                                                                                                                                                                                                                                                                                      | 5-7<br>RSTNMS    | Reset Notification Bus Master. This 3-bit read-only field records the logical number of the bus master performing the notification reset function. The reset function requires that the two consecutive writes to this register be initiated by the same bus master to succeed. This field is updated each time a write to this register occurs. The association between system bus master port numbers, the associated bus master device and the logical processor number is SoC-specific. See the chip configuration chapter for this information.                                                                                                                                                             |
|                |                                                                                                                                                                                                                                                                                      | 0-7<br>RSTNDP    | Reset Notification Data Pattern. This write-only field is accessed with the specified data patterns on the two consecutive writes to enable the notification reset mechanism. For the first write, RSTNDP = 0x47 while the second write requires RSTNDP = 0xb8.                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| 8–15<br>RSTNTN | Reset Notification Number. This 8-bit field specifies the specific IRQ notification state machine to be reset. This field is updated by the second write.<br><br>If RSTNTN < 64, then reset the single IRQ notification machine defined by RSTNTN, else reset all the notifications. |                  |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

## 13.4 Functional Description

In this section, the functional operation of the Semaphores module, specifically the state machines of the SEMA4\_GATE<sub>n</sub> and SEMA4\_CP<sub>n</sub>NTF registers are detailed.

### 13.4.1 SEMA4\_GATEn Operation

Recall each of the SEMA4\_GATEn registers implements a 2-bit, 3-state machine. The state transitions for each gate are shown in the following figure.

**Figure 13-26. SEMA4\_GATEn State Machine**

The bus master number is used to identify core processor 0 (cp0) or core processor 1 (cp1). The Standard (or Reduced) Product Platform passes the AHB bus master number (`hmaster[2:0]`) through the AIPS (or AIPS-Lite) controller and drives an `aips_master[2:0]` output to the Semaphores module as an IPS sideband signal.

The state transitions for SEMA4\_GATEn are defined in the following table.

**Table 13-26. SEMA4\_GATEn State Transitions**

| Current State | Next State | Transition | Description                                                                                                         |
|---------------|------------|------------|---------------------------------------------------------------------------------------------------------------------|
| —             | idle       | 1          | Any reset, whether a system reset or an individual gate reset, unconditionally forces the gate into the idle state. |

*Table continues on the next page...*

**Table 13-26. SEMA4\_GATEn State Transitions  
(continued)**

| Current State | Next State | Transition | Description                                                                                                               |
|---------------|------------|------------|---------------------------------------------------------------------------------------------------------------------------|
| idle          | idle       | 2          | Unless a write of the appropriate lock value from the corresponding processor occurs, the gate remains in the idle state. |
| idle          | cp0_lock   | 3          | When a write of the "cp0_lock" data value is initiated by processor 0, the gate transitions into the cp0_lock state.      |
| idle          | cp1_lock   | 4          | When a write of the "cp1_lock" value is initiated by processor 1, the gate transitions into the cp1_lock state.           |
| cp0_lock      | cp0_lock   | 5          | Once in this state, the gate remains here if any attempted write is not from cp0 with the unlock data value.              |
| cp0_lock      | idle       | 6          | The gate returns to the idle (unlocked) state once a write from cp0 with the unlock data value occurs.                    |
| cp1_lock      | cp1_lock   | 7          | Once in this state, the gate remains here if any attempted write is not from cp1 with the unlock data value.              |
| cp1_lock      | idle       | 8          | The gate returns to the idle (unlocked) state once a write from cp1 with the unlock data value occurs.                    |

### 13.4.2 SEMA4\_CPnNTF Operation

The failed lock write notification interrupt request is implemented in a 3-bit, 5-state machine which records failed lock attempts and transitions based on gate locking and unlocking. Two specific states are encoded and program-visible as SEMA4\_CP0NTF[GNn] and SEMA4\_CP1NTF[GNn]. See the following figure.

Figure 13-27. IRQ Notification State Machine

The state transitions of the IRQ notification function are defined in the following. Specific states of this machine are program-visible as the SEMA4\_CPnNTF registers. In particular, two states are program-visible:

```

if state = wait4_cp0_lock (0b110) // generate cp0_semaphore_int if properly enabled
    then SEMA4_CP0NTF[GNn] = 1; else SEMA4_CP0NTF[GNn] = 0
if state = wait4_cp1_lock (0b101) // generate cp1_semaphore_int if properly enabled
    then SEMA4_CP1NTF[GNn] = 1; else SEMA4_CP1NTF[GNn] = 0
  
```

**Table 13-27. IRQ Notification State Transitions**

| Current State    | Next State       | Transition | Description                                                                                                                                                                                                              |
|------------------|------------------|------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| —                | idle             | 1          | Any reset, including a system reset or an individual notification or secure gate reset, unconditionally forces the machine into the idle state.                                                                          |
| idle             | idle             | 2          | Unless a write of the appropriate lock value from the corresponding processor to an already-locked gate occurs, the machine remains in the idle state.                                                                   |
| idle             | wait4_cp1_unlock | 3          | When a write of the "cp0_lock" data value is initiated by processor 0 but the gate is already locked by cp1, the machine transitions into this state, where it waits for cp1 to unlock the gate.                         |
| idle             | wait4_cp0_unlock | 4          | When a write of the "cp1_lock" data value is initiated by processor 1 but the gate is already locked by cp0, the machine transitions into this state, where it waits for cp0 to unlock the gate.                         |
| wait4_cp1_unlock | wait4_cp1_unlock | 5          | Once in this state, the machine remains here until the gate is unlocked.                                                                                                                                                 |
| wait4_cp1_unlock | wait4_cp0_lock   | 6          | From this state, the machine transitions into the next state, waiting for cp0 to lock the gate, once it has been unlocked.                                                                                               |
| wait4_cp0_unlock | wait4_cp0_unlock | 7          | Once in this state, the machine remains here until the gate is unlocked.                                                                                                                                                 |
| wait4_cp0_unlock | wait4_cp1_lock   | 8          | From this state, the machine transitions into the next state, waiting for cp1 to lock the gate, once it has been unlocked.                                                                                               |
| wait4_cp0_lock   | wait4_cp0_lock   | 9          | In this state, the machine generates the notification interrupt (if properly-enabled) and remains here until the gate is locked by processor 0 or the gate is again locked by processor 1.                               |
| wait4_cp0_lock   | wait4_cp1_unlock | 10         | In this state, the machine generates the notification interrupt (if properly-enabled) and transitions if the gate is again locked by processor 1. With this transition, the notification interrupt request is negated.   |
| wait4_cp0_lock   | idle             | 11         | In this state, the machine generates the notification interrupt (if properly-enabled) and transitions if the gate is finally locked by processor 0. With this transition, the notification interrupt request is negated. |
| wait4_cp1_lock   | wait4_cp1_lock   | 12         | In this state, the machine generates the notification interrupt (if properly-enabled) and remains here until the gate is locked by processor 1 or the gate is again locked by processor 0.                               |
| wait4_cp1_lock   | wait4_cp0_unlock | 13         | In this state, the machine generates the notification interrupt (if properly-enabled) and transitions if the gate is again locked by processor 0. With this transition, the notification interrupt request is negated.   |
| wait4_cp1_lock   | idle             | 14         | In this state, the machine generates the notification interrupt (if properly-enabled) and transitions if the gate is finally locked by processor 1. With this transition, the notification interrupt request is negated. |

The Semaphores module generates two interrupt request output signals, one per processor, combining the SEMA4\_CPnINE and SEMA4\_CPnNTF registers, where the boolean equations are:

```

cp0_semaphore_int
=   sema4_cp0ine[ine0]    &   sema4_cp0ntf[gn0]
  |   sema4_cp0ine[ine1]    &   sema4_cp0ntf[gn1]
  |   sema4_cp0ine[ine2]    &   sema4_cp0ntf[gn2]
  |   ...
  |   sema4_cp0ine[ine15]   &   sema4_cp0ntf[gn15]
cp1_semaphore_int
=   sema4_cp1ine[ine0]    &   sema4_cp1ntf[gn0]
  |   sema4_cp1ine[ine1]    &   sema4_cp1ntf[gn1]
  |   sema4_cp1ine[ine2]    &   sema4_cp1ntf[gn2]
  |   ...
  |   sema4_cp1ine[ine15]   &   sema4_cp1ntf[gn15]

```

## 13.5 Initialization Information

The reset state of the IPS\_Semaphores module allows it to begin operation without the need for any further initialization. All the internal state machines are cleared by any reset event, allowing the module to immediately begin operation.

## 13.6 Application Information

In an operational multi-core system, most interactions involving the Semaphores module involves reads and writes to the SEMA4\_GATEn registers for implementation of the hardware-enforced software gate functions. Typical code segments for gate functions perform the following operations:

- To lock (close) a gate
  - The processor performs a byte write of "logical\_processor\_number + 1" to gate[i]
  - The processor reads back gate[i] and checks for a value of "logical\_processor\_number + 1"

If the compare indicates the expected value, then the gate is locked; proceed with the protected code segment. If the compare does not indicate the expected value, the lock operation failed; repeat the process beginning with byte write to gate[i] in spin-wait loop, or proceed with another execution path and wait for failed lock interrupt notification.

A simple C-language example of a `gateLock` function is shown in the following figure. This function follows the Hennessy/Patterson example described in [Multi-Core Programming 101: Software Gates](#).

```

#define UNLOCK    0
#define CP0_LOCK  1
#define CP1_LOCK  2

void gateLock (n)
int  n;                /* gate number to lock */
{
    int i;
    int current_value;
    int locked_value;

    i = processor_number(); /* obtain logical CPU number */

    if (i == 0)
        locked_value = CP0_LOCK;
    else
        locked_value = CP1_LOCK;

    /* read the current value of the gate and wait until the state == UNLOCK */
    do {
        current_value = gate[n];
    } while (current_value != UNLOCK);

    /* the current value of the gate == UNLOCK. attempt to lock the gate for this
       processor. spin-wait in this loop until gate ownership is obtained */
    do {
        gate[n] = locked_value; /* write gate with processor_number + 1 */
        current_value = gate[n]; /* read gate to verify ownership was obtained */
    } while (current_value != locked_value);
}

```

**Figure 13-28. Sample gateLock Function**

- To unlock (open) a gate
  - After completing the protected code segment, the locking processor performs a byte write of zeroes to gate[i], opening (unlocking) the gate

A few comments on the logical CPU number are appropriate. In this example, a reference to `processor_number()` is used to retrieve this hardware configuration value. Typically, the logical processor numbers are defined by a hardwired input vector to the individual cores. The exact method for accessing the logical processor number varies by architecture. For PowerPC cores, there is a processor ID register (PIR) which is SPR 286 and contains this value. A single instruction can be used to move the contents of the PIR into a general-purpose register: `mf spr rx, 286` where `rx` is the destination GPRn. Other architectures may support a specific instruction to move the contents of the logical processor number into a general-purpose register, e.g., `rdcpn rx` for a "read CPU number" instruction.

If the optional failed lock IRQ notification mechanisms are used, then accesses to the related registers (SEMA4\_CPnINE, SEMA4\_CPnNTF) are required. Note that there is no required negation of the failed lock write notification interrupt as the request is automatically negated by the Semaphores module once the gate has been successfully locked by the "failing" processor.

Finally, in the event a system state requires a software-controlled reset of a gate or IRQ notification register(s), accesses to the secure reset control registers (SEMA4\_RSTGT, SEMA4\_RSTNTF) are required. For these situations, it is recommended that the appropriate IRQ notification enable(s) (SEMA4\_CPnINE) bits be disabled *before* initiating the secure reset 2-write sequence to avoid any race conditions involving spurious notification interrupt requests.

# Chapter 14

## Memory Protection Unit (MPU)

### 14.1 Chip-specific MPU information

This chip has two instances of the MPU module. Some feature details vary between the instances.

The following table summarizes the feature differences. The table does not list feature details that the instances share.

**Table 14-1. MPU instance feature differences**

| Feature                         | MPU_0                  | MPU_1             |
|---------------------------------|------------------------|-------------------|
| Number of slave ports supported | Three numbered 0, 1, 2 | Two numbered 1, 2 |

#### 14.1.1 MPU master and slave assignments

The MPU identifies each XBAR master in terms of the master's logical ID. See the "Logical master ID" assignments in [Table 9-1](#).

Each MPU slave port mediates between an XBAR physical slave port and the module that is assigned to that physical slave port. For each MPU instance, the following tables show the alignment among the MPU slave ports, the XBAR physical slave ports, and the corresponding assigned modules.

**Table 14-2. MPU\_0 slave ports**

| MPU_0 slave port | XBAR physical slave port | Module assigned to XBAR physical slave port |
|------------------|--------------------------|---------------------------------------------|
| 1                | 2                        | PRAMC_0                                     |
| 2                | 6                        | AIPS_1 (Peripheral Bridge A)                |

**Table 14-3. MPU\_1 slave ports**

| MPU_1 slave port | XBAR physical slave port | Module assigned to XBAR physical slave port |
|------------------|--------------------------|---------------------------------------------|
| 1                | 4                        | PRAMC_1                                     |
| 2                | 7                        | AIPS_0 (Peripheral Bridge B)                |

## 14.1.2 MPU register reset values

The following table lists MPU register reset values that are specific to this chip. For the reset values of all other MPU registers, see [Memory map/register definition](#).

**Table 14-4. Chip-specific MPU register reset values**

| Register | MPU_0 and MPU_1 reset value | Notes                                  |
|----------|-----------------------------|----------------------------------------|
| CESR     | 0081_3200h                  | NSP field resets to 0011b <sup>1</sup> |

1. CESR[NSP]'s reset value on MPU\_1 is 3 even though MPU\_1 has only two slave ports.

## 14.2 Introduction

The memory protection unit (MPU) provides hardware access control for all memory references generated in the device.

## 14.3 Overview

The MPU concurrently monitors all system bus transactions and evaluates their appropriateness using pre-programmed region descriptors that define memory spaces and their access rights. Memory references that have sufficient access control rights are allowed to complete, while references that are not mapped to any region descriptor or have insufficient rights are terminated with a protection error response.

### 14.3.1 Block diagram

A simplified block diagram of the MPU module is shown in the following figure.

**Figure 14-1. MPU block diagram**

The hardware's two-dimensional connection matrix is clearly visible with the basic access evaluation macro shown as the replicated submodule block. The crossbar switch slave ports are shown on the left, the region descriptor registers in the middle, and the peripheral bus interface on the right side. The evaluation macro contains two magnitude comparators connected to the start and end address registers from each region descriptor as well as the combinational logic blocks to determine the region hit and the access protection error. For details of the access evaluation macro, see [Access evaluation macro](#).

## 14.3.2 Features

The MPU implements a two-dimensional hardware array of memory region descriptors and the crossbar slave ports to continuously monitor the legality of every memory reference generated by each bus master in the system.

The feature set includes:

- 12 program-visible 128-bit region descriptors, accessible by four 32-bit words each
  - Each region descriptor defines a modulo-32 byte space, aligned anywhere in memory

- Region sizes can vary from 32 bytes to 4 Gbytes
- Two access control permissions defined in a single descriptor word
  - Masters 0–3: read, write, and execute attributes for supervisor and user accesses
  - Masters 4–7: read and write attributes
- Hardware-assisted maintenance of the descriptor valid bit minimizes coherency issues
- Alternate programming model view of the access control permissions word
- Priority given to granting permission over denying access for overlapping region descriptors
- Detects access protection errors if a memory reference does not hit in any memory region, or if the reference is illegal in all hit memory regions. If an access error occurs, the reference is terminated with an error response, and the MPU inhibits the bus cycle being sent to the targeted slave device.
- Error registers, per slave port, capture the last faulting address, attributes, and other information
- Global MPU enable/disable control bit

## 14.4 Memory map/register definition

The programming model is partitioned into three groups:

- Control/status registers
- The data structure containing the region descriptors
- The alternate view of the region descriptor access control values

The programming model can be referenced using only 32-bit accesses.

Attempted references of the following types generate an error termination:

- Non-32-bit references
- References to undefined—that is, reserved—addresses
- References with a non-supported access type, such as a write access to a read-only register or a read access of a write-only register

**NOTE**

See the chip configuration details for any chip-specific register information in this module.

**MPU memory map**

| Address offset (hex) | Register name                                   | Width (in bits) | Access | Reset value                 | Section/ page              |

**14.4.2 Error Address Register, slave port n (MPU\_EAR<sub>n</sub>)**

When the MPU detects an access error on slave port n, the 32-bit reference address is captured in this read-only register and the corresponding bit in CESR[SPERR<sub>n</sub>] is set. Additional information about the faulting access is captured in the corresponding EDR<sub>n</sub> at the same time. This register and the corresponding EDR<sub>n</sub> contain the most recent access error; there are no hardware interlocks with CESR[SPERR<sub>n</sub>], as the error registers are always loaded upon the occurrence of each protection violation.

### 14.4.3 Error Detail Register, slave port n (MPU\_EDRn)

When the MPU detects an access error on slave port n, 32 bits of error detail are captured in this read-only register and the corresponding bit in CESR[SPERRn] is set. Information on the faulting address is captured in the corresponding EARN register at the same time. This register and the corresponding EARN register contain the most recent access error; there are no hardware interlocks with CESR[SPERRn] as the error registers are always loaded upon the occurrence of each protection violation.

**MPU\_RGDn\_WORD1 field descriptions**

| Field             | Description                                                                                                                                                                              |
|-------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–26<br>ENDADDR   | End Address<br><br>Defines the most significant bits of the 31-modulo-32 byte end address of the memory region.<br><br><b>NOTE:</b> The MPU does not verify that ENDADDR $\geq$ SRTADDR. |
| 27–31<br>Reserved | This field is reserved.                                                                                                                                                                  |

**14.4.6 Region Descriptor n, Word 2 (MPU\_RGDn\_WORD2)**

The third word of the region descriptor defines the access control rights of the memory region. The access control privileges depend on two broad classifications of bus masters:

- Bus masters 0–3 have a 5-bit field defining separate privilege rights for user and supervisor mode accesses. Each of these bus masters optionally includes a process identification field (if implemented for the master) within the definition.
- Bus masters 4–7 are limited to separate read and write permissions.

For the privilege rights of bus masters 0–3, there are three flags associated with this function:

- Read (r) refers to accessing the referenced memory address using an operand (data) fetch
- Write (w) refers to updating the referenced memory address using a store (data) instruction
- Execute (x) refers to reading the referenced memory address using an instruction fetch

Writes to RGDn\_WORD2 clear the region descriptor's valid bit (RGDn\_WORD3[VLD]). If only updating the access controls, write to RGDAACn instead because stores to these locations do not affect the descriptor's valid bit.

Address: 0h base + 408h offset + (16d  $\times$  i), where i=0d to 11d

14.4.7 Region Descriptor n, Word 3 (MPU\_RGDn\_WORD3)

The fourth word of the region descriptor contains the optional process identifier and mask, plus the region descriptor’s valid bit.

Address: 0h base + 40Ch offset + (16d × i), where i=0d to 11d

Any write to RGDn_WORD0–2 clears this bit.<br><br>0   Region descriptor is invalid<br>1   Region descriptor is valid                                                                                                                                                                                                                                                                                 |

### 14.4.8 Region Descriptor Alternate Access Control n (MPU\_RGDAACn)

Because software may adjust only the access controls within a region descriptor (RGDn\_WORD2) as different tasks execute, an alternate programming view of this 32-bit entity is available. Writing to this register does not affect the descriptor's valid bit.

Address: 0h base + 800h offset + (4d × i), where i=0d to 11d

## 14.5 Functional description

In this section, the functional operation of the MPU is detailed, including the operation of the access evaluation macro and the handling of error-terminated bus cycles.

### 14.5.1 Access evaluation macro

The basic operation of the MPU is performed in the access evaluation macro, a hardware structure replicated in the two-dimensional connection matrix. As shown in the following figure, the access evaluation macro inputs the crossbar bus address phase signals and the contents of a region descriptor (RGD<sub>n</sub>) and performs two major functions:

- Region hit determination
- Detection of an access protection violation

The following figure shows a functional block diagram.

**Figure 14-76. MPU access evaluation macro**

### 14.5.1.1 Hit determination

To determine whether the current reference hits in the given region, two magnitude comparators are used with the region's start and end addresses. The boolean equation for this portion of the hit determination is:

```
region_hit = ((addr[31:5] >= RGDn_Word0[SRTADDR]) & (addr[31:5] <= RGDn_Word1[ENDADDR])) &
RGDn_Word3[VLD]
```

where *addr* is the current reference address, *RGDn\_Word0[SRTADDR]* and *RGDn\_Word1[ENDADDR]* are the start and end addresses, and *RGDn\_Word3[VLD]* is the valid bit.

#### NOTE

The MPU does not verify that *ENDADDR* ≥ *SRTADDR*.

In addition to the comparison of the reference address versus the region descriptor's start and end addresses, the optional process identifier is examined against the region descriptor's PID and PIDMASK fields. A process identifier hit term is formed as follows:

```
pid_hit = ~RGDn_Word2[MxPE] |
((current_pid |
RGDn_Word3[PIDMASK]) == (RGDn_Word3[PID] | RGDn_Word3[PIDMASK]))
```

where the *current\_pid* is the selected process identifier from the current bus master, and *RGDn\_Word3[PID]* and *RGDn\_Word3[PIDMASK]* are the process identifier fields from region descriptor *n*. For bus masters that do not output a process identifier, the MPU forces the *pid\_hit* term to assert.

### 14.5.1.2 Privilege violation determination

While the access evaluation macro is determining region hit, the logic is also evaluating if the current access is allowed by the permissions defined in the region descriptor. Using the master and supervisor/user mode signals, a set of effective permissions is generated from the appropriate fields in the region descriptor. The protection violation logic then evaluates the access against the effective permissions using the specification shown below.

**Table 14-80. Protection violation definition**

| Description            | MxUM |   |   | Protection violation?      |
|------------------------|------|---|---|----------------------------|
|                        | r    | w | x |                            |
| Instruction fetch read | —    | — | 0 | Yes, no execute permission |
|                        | —    | — | 1 | No, access is allowed      |
| Data read              | 0    | — | — | Yes, no read permission    |
|                        | 1    | — | — | No, access is allowed      |
| Data write             | —    | 0 | — | Yes, no write permission   |
|                        | —    | 1 | — | No, access is allowed      |

### 14.5.2 Putting it all together and error terminations

For each slave port monitored, the MPU performs a reduction-AND of all the individual terms from each access evaluation macro. This expression then terminates the bus cycle with an error and reports a protection error for three conditions:

- If the access does not hit in any region descriptor, a protection error is reported.
- If the access hits in a single region descriptor and that region signals a protection violation, a protection error is reported.
- If the access hits in multiple (overlapping) regions and all regions signal protection violations, a protection error is reported.

As shown in the third condition, granting permission is a higher priority than denying access for overlapping regions. This approach is more flexible to system software in region descriptor assignments. For an example of the use of overlapping region descriptors, see [Application information](#).

### 14.5.3 Power management

Disabling the MPU by clearing CESR[VLD] minimizes power dissipation. To minimize the power dissipation of an enabled MPU, invalidate unused region descriptors by clearing the associated RGDn\_Word3[VLD] bits.

## 14.6 Initialization information

At system startup, load the appropriate number of region descriptors, including setting RGDn\_Word3[VLD]. Setting CESR[VLD] enables the module.

If the system requires that all the loaded region descriptors be enabled simultaneously, first ensure that the entire MPU is disabled (CESR[VLD]=0).

### Note

A region descriptor must be set to allow access to the MPU registers if further changes are needed.

## 14.7 Application information

In an operational system, interfacing with the MPU is generally classified into the following activities:

- Creating a new memory region—Load the appropriate region descriptor into an available RGDn, using four sequential 32-bit writes. The hardware assists in the maintenance of the valid bit, so if this approach is followed, there are no coherency issues with the multi-cycle descriptor writes. (Clearing RGDn\_Word3[VLD] deletes/removes an existing memory region.)
- Altering only access privileges—To not affect the valid bit, write to the alternate version of the access control word (RGDAACn), so there are no coherency issues involved with the update. When the write completes, the memory region's access rights switch instantaneously to the new value.
- Changing a region's start and end addresses—Write a minimum of three words to the region descriptor (RGDn\_Word{0,1,3}). Word 0 and 1 redefine the start and end addresses, respectively. Word 3 re-enables the region descriptor valid bit. In most situations, all four words of the region descriptor are rewritten.
- Accessing the MPU—Allocate a region descriptor to restrict MPU access to supervisor mode from a specific master.

- Detecting an access error—The current bus cycle is terminated with an error response and  $EAR_n$  and  $EDR_n$  capture information on the faulting reference. The error-terminated bus cycle typically initiates an error response in the originating bus master. For example, a processor core may respond with a bus error exception, while a data movement bus master may respond with an error interrupt. The processor can retrieve the captured error address and detail information simply by reading  $E\{A,D\}R_n$ .  $CESR[SPERR]$  signals which error registers contain captured fault data.
- Overlapping region descriptors—Applying overlapping regions often reduces the number of descriptors required for a given set of access controls. In the overlapping memory space, the protection rights of the corresponding region descriptors are logically summed together (the boolean OR operator).

The following dual-core system example contains four bus masters:

- The two processors: CP0, CP1
- Two DMA engines: DMA1, a traditional data movement engine transferring data between RAM and peripherals and DMA2, a second engine transferring data to/from the RAM only

Consider the following region descriptor assignments:

**Table 14-81. Overlapping region descriptor example**

| Region description    | RGDn |   | CP0 | CP1 | DMA1 | DMA2 |                  |
|-----------------------|------|---|-----|-----|------|------|------------------|
| CP0 code              | 0    |   | rwX | r-- | —    | —    | Flash            |
| CP1 code              | 1    |   | r-- | rwX | —    | —    |                  |
| CP0 data & stack      | 2    |   | rw- | —   | —    | —    | RAM              |
| CP0 → CP1 shared data | 2    | 3 | r-- | r-- | —    | —    |                  |
| CP1 → CP0 shared data | 4    |   |     |     |      |      |                  |
| CP1 data & stack      | 4    |   | —   | rw- | —    | —    |                  |
| Shared DMA data       | 5    |   | rw- | rw- | rw   | rw   |                  |
| MPU                   | 6    |   | rw- | rw- | —    | —    |                  |
| Peripherals           | 7    |   | rw- | rw- | rw   | —    | Peripheral space |

In this example, there are eight descriptors used to span nine regions in the three main spaces of the system memory map: flash, RAM, and peripheral space. Each region indicates the specific permissions for each of the four bus masters and this definition provides an appropriate set of shared, private and executable memory spaces.

Of particular interest are the two overlapping spaces: region descriptors 2 & 3 and 3 & 4.

The space defined by RGD2 with no overlap is a private data and stack area that provides read/write access to CP0 only. The overlapping space between RGD2 and RGD3 defines a shared data space for passing data from CP0 to CP1 and the access controls are defined by the logical OR of the two region descriptors. Thus, CP0 has (rw- | r--) = (rw-) permissions, while CP1 has (--- | r--) = (r--) permission in this space. Both DMA engines are excluded from this shared processor data region. The overlapping spaces between RGD3 and RGD4 defines another shared data space, this one for passing data from CP1 to CP0. For this overlapping space, CP0 has (r-- | ---) = (r--) permission, while CP1 has (rw- | r--) = (rw-) permission. The non-overlapped space of RGD4 defines a private data and stack area for CP1 only.

The space defined by RGD5 is a shared data region, accessible by all four bus masters. Finally, the slave peripheral space mapped onto the IPS bus is partitioned into two regions:

- One containing the MPU's programming model accessible only to the two processor cores
- The remaining peripheral region accessible to both processors and the traditional DMA1 master

This example shows one possible application of the capabilities of the MPU in a typical system.

# Chapter 15

## Interrupt Controller (INTC)

### 15.1 Chip-specific INTC information

The INTC on this chip supports two core processors. In the detailed INTC description, the cores are designated processor 0 and processor 1.

### 15.2 Introduction

The INTC:

- Provides priority-based preemptive scheduling of interrupt requests
- Schedules interrupt requests (IRQs) from software and internal peripherals to one or both processors (PRCs)
- Provides interrupt prioritization and preemption, interrupt masking, interrupt priority elevation, and protocol support

The INTC has two independent sets of priority arbitration/comparison, request selection, vector encoder and acknowledge logic—one set for each CPU. This arrangement allows each CPU to handle its software-assigned interrupt requests independently of the other CPU's operation, and it provides flexibility for the user to decide which core should handle which interrupt sources in the application. This flexibility comes from a set of configuration bits that allows any interrupt source to generate an interrupt request to Core 0, Core 1, or both cores.

For high-priority interrupt requests in these target applications, it is necessary to minimize the interval between the assertion of the interrupt request from the peripheral and the point at which the processor is performing useful work to service the interrupt request. The INTC supports this goal by providing a unique vector for each interrupt request source. It also provides 16 priorities so that lower priority ISRs do not delay the

execution of higher priority ISRs. Since each individual application will have different priorities for each source of interrupt request, the priority of each interrupt request is configurable.

When multiple tasks share a resource, coherent accesses to that resource need to be supported. The INTC supports the Priority Ceiling Protocol for coherent accesses. By providing a modifiable priority mask, the priority can be raised temporarily so that all tasks which share the resource are unable to preempt each other.

Multiple processors can assert interrupt requests to each other through software-settable interrupt requests. These same software-settable interrupt requests can also be used to separate the work involved in servicing an interrupt request into two parts, a high-priority portion and a low-priority portion. The high-priority portion is initiated by a peripheral interrupt request, but then the ISR can assert a software-settable interrupt request to finish the servicing in a lower priority ISR. Therefore these software-settable interrupt requests can be used instead of having the peripheral ISR schedule a task through the RTOS.

## 15.3 Block diagram

Interrupts implemented by the chip are defined in the *e200z759n3 Core Reference Manual*.

The block diagram for the INTC appears in the following figure.

Figure 15-1. INTC block diagram

## 15.4 Features

- Each peripheral interrupt source is software-steerable to interrupt request outputs of processor 0, processor 1, or both
- 8 software-settable interrupt request sources
- 9-bit vector
  - Unique vector for each interrupt request source
  - Hardware connection to processor or read from register
- Each interrupt source can be programmed to one of 16 priorities
- Each interrupt source can be triggered by software
- Preemption
  - Preemptive prioritized interrupt requests to processor
  - ISR with higher priority preempts ISRs or tasks with lower priorities
  - Automatic pushing or popping of preempted priority to or from a LIFO
  - Ability to modify the ISR or task priority; modifying the priority can be used to implement the Priority Ceiling Protocol for accessing shared resources
- Low latency
  - Three INTC clock cycles from receipt of interrupt request from peripheral to interrupt request to processor

## 15.5 Modes of operation

The interrupt controller has two handshaking modes with the processor: software vector mode and hardware vector mode. The state of the hardware vector enable bit, `INTC_MCR[HVEN_PRC $n$ ]`, determines which mode is used for each CPU.

In debug mode the interrupt controller operation is identical to its normal operation of software vector mode or hardware vector mode.

## 15.5.1 Software vector mode

In software vector mode, as shown in the following figure, the CPU branches to a common interrupt exception handler whose location is determined by an address derived from special purpose registers IVPR and IVOR4. The interrupt exception handler reads the INTC\_IACKR\_PCR $n$  to determine the vector of the interrupt request source.

**Figure 15-2. INTC software vector mode**

The following figure shows the typical program flow for software vector mode.

N is the maximum number of usable interrupt vectors and includes eight software-settable IRQ vectors.

**Figure 15-3. Program flow: software vector mode**

The following figure shows how the common interrupt exception handler address is calculated by hardware. The upper half of the interrupt vector prefix register (IVPR) is added to the offset contained in the external input interrupt vector offset register (IVOR4). Because bits IVOR4[28:31] are not part of the offset value, the vector offset must be in a location in memory that is quad-word (16-byte) aligned.

## Modes of operation

**Figure 15-4. Software vector mode: interrupt exception handler address calculation**

As shown in the preceding figure, the common interrupt exception handler reads the `INTC_IACKR_PRCn` to determine the vector of the interrupt request source. The `INTC_IACKR_PRCn` register contains a 32-bit address for a vector table base address (VTBA) plus an offset to access the interrupt vector (INTVEC). The address is then used to branch to the corresponding routine for that peripheral or software interrupt source.

Reading the `INTC_IACKR_PRCn` acknowledges the INTC's interrupt request and negates the interrupt request to the processor. The interrupt request to the processor does not clear if a higher priority interrupt request arrives. Even in this case, INTVEC does not update to the higher priority request until the lower priority interrupt request is acknowledged by reading the `INTC_IACKR_PRCn`. The reading also pushes the PRI value in the INTC current priority register (`INTC_CPR_PRCn`) onto the LIFO and updates PRI in the `INTC_CPR_PRCn` with the priority of the interrupt request. The `INTC_CPR_PRCn` masks any peripheral or software settable interrupt request at the same or lower priority of the current value of the PRI field in `INTC_CPR_PRCn` from generating an interrupt request to the processor.

The interrupt exception handler must write to the end-of-interrupt register (`INTC_EOIR_PRCn`) to complete the operation. Writing to the `INTC_EOIR_PRCn` ends the servicing of the interrupt request. The INTC's LIFO is popped into the `INTC_CPR_PRCn`'s PRI field by writing to the `INTC_EOIR_PRCn`, and the size of a write does not affect the operation of the write. Those values and sizes written to this register neither update the `INTC_EOIR_PRCn` contents nor affect whether the LIFO pops. For possible future compatibility, write four bytes of all zeroes to the `INTC_EOIR_PRCn`. The timing relationship between popping the LIFO and disabling recognition of external input has no restriction. The writes can happen in either order.

However, disabling recognition of the external input before popping the LIFO eases the calculation of the maximum stack depth at the cost of postponing the servicing of the next interrupt request.

## 15.5.2 Hardware vector mode

The following figure shows the typical program flow for hardware vector mode.

N is the maximum number of usable interrupt vectors and includes eight software-settable IRQ vectors.

**Figure 15-5. Program flow: hardware vector mode**

In hardware vector mode, the interrupt exception handler address is specific to the peripheral or software-settable interrupt source rather than being common to all of them. No IVOR is used. The interrupt exception handler address is calculated by hardware as shown in the following figure. The upper half of the interrupt vector prefix register (IVPR) is added to an offset, which corresponds to the peripheral or software interrupt source which caused the interrupt request. The offset matches the value in the Interrupt Vector field, INTC\_IACKR\_PRCn[INTVEC]. Each interrupt exception handler address is aligned on a quad word (16-byte) boundary. IVOR4 is not used in this mode, and software does not need to read INTC\_IACKR\_PRCn to get the interrupt vector number.

**Figure 15-6. Hardware vector mode: interrupt exception handler address calculation**

The processor negates INTC's interrupt request when automatically acknowledging the interrupt request. However, the interrupt request to the processor do not negate if a higher priority interrupt request arrives. Even in this case, the interrupt vector number does not update to the higher priority request until the lower priority request is acknowledged by the processor.

The assertion of the interrupt acknowledge signal pushes the PRI value in the INTC\_CPR\_PRC $n$  onto the LIFO and updates PRI in the INTC\_CPR\_PRC $n$  with the new priority.

## 15.6 External signal description

The INTC has no direct external MCU signals. However, there are external pins that can be configured in the SIU as external interrupt request input pins. When configured in this function, an interrupt on the pin sets an external interrupt flag. These flags can cause one of five peripheral interrupt requests to the interrupt controller.

## 15.7 Memory map and register definition

The actual availability and number of registers are chip-specific. For this information, see the chapter that describes how modules are configured and connected.

### NOTE

For unimplemented locations in the memory map, read accesses return zeros and attempted write accesses are ignored.

The INTC register memory map is mirrored at 1 KB intervals. Referring to the following equation, the result of accessing any location when I is 1 to 15 is the same as the result of accessing a location when I is 0:

Offset + (400h x I), where I = 0 to 15

For example: PSR0 is accessed at 040h, 440h, 840h, and so on.

With the exception of the INTC\_SSCIR $n$  and INTC\_PSR $n$  registers, all of the registers are 32-bit. Any combination of accessing the four bytes of a register with a single access is supported, provided that the access does not cross a register boundary. These supported accesses include types and sizes of 8 bits, aligned 16 bits, misaligned 16 bits to the middle two bytes, and aligned 32 bits.

Although INTC\_SSCIR $n$  and INTC\_PSR $n$  are 8 bits wide, they can be accessed with a single 16-bit or 32-bit access, provided that the access does not cross a 32-bit boundary.

In software vector mode, the effects of a read of the INTC Interrupt Acknowledge register are the same regardless of the size of the read. In either software or hardware vector mode, the size of a write to the INTC End-of-Interrupt register does not affect the operation of the write.

### INTC memory map

| Address offset (hex) | Register name                                                         | Width (in bits) | Access | Reset value | Section/ page              |

**15.7.2 INTC Current Priority Register for Processor *n* (INTC\_CPR\_PRC<sub>*n*</sub>)**

The INTC\_CPR\_PRC<sub>*n*</sub> masks any peripheral or software-settable interrupt request that is set at the same or lower priority as the current value of the INTC\_CPR\_PRC<sub>*n*</sub>[PRI] field from generating an interrupt request to the processor. When the INTC Interrupt Acknowledge register (INTC\_IACKR\_PRC<sub>*n*</sub>) is read in software vector mode or the interrupt acknowledge signal from the processor is asserted in hardware vector mode, the value of PRI is pushed onto the LIFO, and PRI is updated with the priority of the preempting interrupt request. When the INTC End-of-Interrupt register (INTC\_EOIR\_PRC<sub>*n*</sub>) is written, the LIFO is popped into the INTC\_CPR\_PRC<sub>*n*</sub>[PRI] field. An exception case in hardware vector mode to this behavior is described in [Hardware vector mode](#).

The masking priority can be raised or lowered by writing to the PRI field, supporting the priority ceiling protocol. See [Priority ceiling protocol](#).

**NOTE**

The PRI register address space must be configured as guarded and cache-inhibited prior to writing to the register.

**NOTE**

A store to modify the PRI field that closely precedes or follows an access to a shared resource may result in a non-coherent access to that resource. See [Ensuring coherency](#) for example code to ensure coherency.

## 15.7.3 INTC Interrupt Acknowledge Register for Processor *n* (INTC\_IACKR\_PRC<sub>n</sub>)

The Interrupt Acknowledge Register for Processor *n* provides a value which can be used to load the address of an ISR from a vector table. The vector table can be composed of addresses of the ISRs specific to their respective interrupt vectors.

### NOTE

Also, in software vector mode, the INTC\_IACKR\_PRC<sub>n</sub> has side effects from reads. Therefore, it must not be read speculatively while in this mode. The side effects are the same regardless of the size of the read.

### NOTE

Reading the INTC\_IACKR\_PRC<sub>n</sub> has no side effects in hardware vector mode (when the corresponding INTC\_MCR[HVEN\_PRC<sub>n</sub>] field is 1).

### NOTE

In software vector mode, the INTC\_IACKR\_PRC<sub>n</sub> must be read before setting MSR[EE]. No synchronization instruction is needed after reading the INTC\_IACKR\_PRC<sub>n</sub> and before setting MSR[EE].

However, the time for the processor to recognize the assertion or negation of the external input to it is not defined by the book E architecture and can be greater than 0. Therefore, insert instructions between the reading of the INTC\_IACKR\_PRC<sub>n</sub> and the setting of MSR[EE] that consumes at least two

processor clock cycles. This length of time allows the interrupt request negation to propagate through the processor before MSR[EE] is set.

## 15.7.4 INTC End Of Interrupt Register for Processor n (INTC\_EOIR\_PRCn)

Writing to the INTC\_EOIR\_PRCn signals the end of the servicing of the interrupt request. When the INTC\_EOIR\_PRCn is written, the priority last pushed on the LIFO is popped into INTC\_CPR\_PRCn. The values and size of data written to the INTC\_EOIR\_PRCn are ignored. Those values and sizes written to this register neither update the INTC\_EOIR\_PRCn contents nor affect whether the LIFO pops. Typically, when you write to this register, write four all-zero bytes.

**15.7.5 INTC Software Set/Clear Interrupt Register (INTC\_SSCIRn)**

The INTC\_SSCIR registers support the setting or clearing of software-settable interrupt requests. These registers contain independent sets of bits to set and clear a corresponding flag bit by software. With the exception of being set by software, this flag bit behaves the same as a flag bit set within a peripheral. This flag bit generates an interrupt request within the INTC just like a peripheral interrupt request. Writing a 1 to SETn will leave SETn unchanged at 0 but will set CLRn. Writing a 0 to SETn will have no effect. CLRn is the flag bit. Writing a 1 to CLRn will clear it. Writing a 0 to CLRn will have no effect. If a 1 is written to a pair of SETn and CLRn bits at the same time, CLRn is asserted, regardless of whether CLRn was asserted before the write.

Address: 0h base + 20h offset + (1d × i), where i=0d to 7d

**INTC\_SSCIRn field descriptions**

| Field           | Description                                                                                                                                                                                                                                                                                      |
|-----------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–5<br>Reserved | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                          |
| 6<br>SETn       | Set flag bits. Writing a 1 will set the corresponding CLRn bit. Writing a 0 will have no effect. Each SETn is read as a 0.                                                                                                                                                                       |
| 7<br>CLRn       | Clear flag bits. CLRn is the flag bit. Writing a 1 to CLRn will clear it provided that a 1 is not written simultaneously to its corresponding SETn bit. Writing a 0 to CLRn will have no effect.<br><br>0 Interrupt request not pending within INTC.<br>1 Interrupt request pending within INTC. |

### 15.7.6 INTC Priority Select Register (INTC\_PSRn)

The Priority Select Registers support the selection of an individual priority for each source of interrupt request, and the routing of the request to one or both processors. The unique vector of each peripheral or software-settable interrupt request determines which INTC\_PSRn is assigned to that interrupt request. The software-settable interrupt requests 0–7 are assigned vectors 0–7, and their priorities are configured in INTC\_PSR0 to INTC\_PSR7, respectively. The peripheral interrupt requests are assigned to vectors in the range 8 to 511, and their priorities are configured in the range of registers INTC\_PSR8 to INTC\_PSR511, respectively.

**NOTE**

Interrupts are not detected while the PSRs are being written.  
The PRC\_SELn or PRIn field of an INTC\_PSRn must not be modified while the corresponding peripheral or software settable interrupt request is asserted.

Address: 0h base + 40h offset + (1d × i), where i=0d to 511d

## 15.8 Functional description

The functional description involves the areas of interrupt request sources, priority management, and handshaking with the processor. In addition, spaces in the memory map have been reserved for other possible implementations of the INTC.

## 15.8.1 Interrupt request sources

The INTC has two types of interrupt requests, peripheral and software-settable. These interrupt requests can assert on any clock cycle.

The INTC has no spurious vector support. Therefore, if an asserted peripheral or software-settable interrupt request, whose  $PRI_n$  value in  $INTC\_PSR_n$  is higher than the  $PRI$  value in  $INTC\_CPR_n$ , negates before the interrupt request to the processor for that peripheral or software-settable interrupt request is acknowledged, then the interrupt request to the processor still can assert (or will remain asserted) for that peripheral or software-settable interrupt request. In this case, the interrupt vector will correspond to that peripheral or software-settable interrupt request. Also, the  $PRI$  value in the associated  $INTC\_CPR_n$  is updated with the corresponding  $PRI_n$  value in  $INTC\_PSR_n$ .

Furthermore, clearing the peripheral interrupt request's enable bit in the peripheral, or (alternatively) setting its mask bit, has the same consequences as clearing its flag bit. Setting its enable bit or clearing its mask bit while its flag bit is asserted has the same effect on the INTC as an interrupt event setting the flag bit.

### 15.8.1.1 Peripheral interrupt requests

An interrupt event in a peripheral's hardware sets a flag bit which resides in that peripheral. The interrupt request from the peripheral is driven by that flag bit.

The time from when the peripheral starts to drive its peripheral interrupt request to the INTC, to the time that the INTC starts to drive the interrupt request to the processor, is three clocks.

Interrupt requests from devices external to this chip are classified as peripheral interrupt requests in this document. This type of external peripheral interrupts is handled by the SIU.

### 15.8.1.2 Software-settable interrupt requests

The software set/clear interrupt registers ( $INTC\_SSCIR_n$ ) support the setting or clearing of software-settable interrupt requests. These registers contain independent sets of bits to set and clear a corresponding flag bit by software. An interrupt request is triggered by software by writing a 1 to a  $SET_n$  bit in  $INTC\_SSCIR_n$ . This write sets the corresponding  $CLR_n$  bit, which is a flag bit, resulting in the interrupt request. The interrupt request is cleared by writing a 1 to the  $CLR_n$  bit. Specific behavior includes the following:

- Writing a 1 to SET $n$  leaves SET $n$  unchanged at 0 but sets the flag bit (which is the CLR $n$  bit).
- Writing a 0 to SET $n$  has no effect.
- Writing a 1 to CLR $n$  clears the flag (CLR $n$ ) bit.
- Writing a 0 to CLR $n$  has no effect.
- If a 1 is written to a pair of SET $n$  and CLR $n$  bits at the same time, the flag (CLR $n$ ) is set, regardless of whether CLR $n$  was asserted before the write.

The time from the write to the SET $n$  bit, to the time that the INTC starts to drive the interrupt request to the processor, is four clocks.

### 15.8.1.3 Unique vector for each interrupt request source

Each peripheral and software-settable interrupt request is assigned a hardwired unique 9-bit vector. Software-settable interrupts 0–7 are assigned vectors 0–7, respectively. The peripheral interrupt requests are assigned vectors from 8 to a number as high as needed to cover all peripheral interrupt requests.

## 15.8.2 Priority management

The asserted interrupt requests are compared to each other based on their PRI $n$  and PRC\_SEL $n$  values set in INTC\_PSR $n$ . The result of that comparison also is compared to PRI in the associated INTC\_CPR $n$ . The results of those comparisons are used to manage the priority of the ISR being executed by the associated processor. The associated LIFO also assists in managing that priority.

### 15.8.2.1 Current priority and preemption

The priority arbitrator, selector, encoder, and comparator logic shown in [Figure 15-1](#) are used to compare the priority of the asserted interrupt requests to the current priority. If the priority of any asserted peripheral or software-settable interrupt request is higher than the current priority for a given processor, then the interrupt request to the processor is asserted. Also, a unique vector for the preempting peripheral or software-settable interrupt request is generated for the associated INTC\_IACKR $n$ , and if in hardware vector mode, for the interrupt vector provided to the processor.

### 15.8.2.1.1 Priority arbitrator

The priority arbitrator for each processor compares all the priorities of all of the asserted interrupt requests assigned to that processor, both peripheral and software-settable. The output of the priority arbitrator is the highest of those priorities assigned to a given processor. Also, any interrupt requests which have this highest priority are output as asserted interrupt requests to the associated selector logic.

### 15.8.2.1.2 Selector

If only one interrupt request from the associated priority arbitrator is asserted, then it is passed as asserted to the associated encoder logic. If multiple interrupt requests from the associated priority arbitrator are asserted, then only the one with the lowest vector is passed as asserted to the associated encoder logic. The lower vector is chosen regardless of the time order of the assertions of the peripheral or software-settable interrupt requests.

### 15.8.2.1.3 Encoder

The encoder logic generates the unique 9-bit vector for the asserted interrupt request from the request selector submodule for the associated processor.

### 15.8.2.1.4 Comparator

The comparator logic compares the highest priority output from the associated priority arbitrator subblock with PRI in the associated INTC\_CPR $n$ . If the comparator detects that this highest priority is higher than the current priority, then it asserts the interrupt request to the associated processor. This interrupt request to the processor asserts whether this highest priority is raised above the value of PRI in the associated INTC\_CPR $n$ , or the PRI value in the associated INTC\_CPR $n$  is lowered below this highest priority. This highest priority then becomes the new priority which is written to PRI in the associated INTC\_CPR $n$  when the interrupt request to the processor is acknowledged. Interrupt requests whose PRI $n$  in INTC\_PSR $n$  are zero will not cause a preemption because their PRI $n$  will not be higher than PRI in the associated INTC\_CPR $n$ .

Another function of the comparator is to signal an update of the INTC\_IACKR $n$  with the vector number of the first interrupt that arrives that has a priority higher than the current priority. Once the vector number and priority are captured, they cannot be superseded by a higher priority interrupt until an update of the INTC\_CPR $n$  occurs.

One consequence of the priority comparator design is that once a higher priority interrupt is captured, it must be acknowledged by the CPU before a subsequent interrupt request of even higher priority can be captured. For example, if the CPU is executing a priority level

1 interrupt, and a priority level 2 interrupt request is captured by the INTC, followed shortly by a priority level 3 interrupt request to the INTC, the level 2 interrupt must be acknowledged by the CPU before a new level 3 interrupt will be generated.

### 15.8.2.2 Stack (LIFO)

The LIFO stores the preempted PRI values from the associated INTC\_CPR $n$ . Therefore, because these priorities are stacked within the INTC, if interrupts need to be enabled during the ISR, at the beginning of the interrupt exception handler the PRI value in the associated INTC\_CPR $n$  does not need to be loaded from the associated INTC\_CPR $n$  and stored onto the context stack. Likewise at the end of the interrupt exception handler, the priority does not need to be loaded from the context stack and stored into the associated INTC\_CPR $n$ .

The PRI value in the associated INTC\_CPR $n$  is pushed onto the LIFO when the associated INTC\_IACKR $n$  is read in software vector mode or the interrupt acknowledge signal from the associated processor is asserted in hardware vector mode. The priority is popped into PRI in the associated INTC\_CPR $n$  whenever the associated INTC\_EOIR $n$  is written. An exception case in hardware vector mode to this behavior is described in [Hardware vector mode](#).

Although the INTC supports 16 priorities, an ISR executing with PRI in the INTC\_CPR $n$  equal to 15 will not be preempted. Therefore, the LIFO supports the stacking of 15 priorities. However, the LIFO is only 14 entries deep. An entry for a priority of 0 is not needed because of the ways that pushing onto a full LIFO and popping an empty LIFO are treated. If the LIFO is pushed 15 or more times than it is popped, the priorities first pushed are overwritten. A priority of 0 would be an overwritten priority. However, the LIFO will pop zeroes if it is popped more times than it is pushed. Therefore, although a priority of 0 was overwritten, it is regenerated with the popping of an empty LIFO.

## 15.8.3 Handshaking with processor

This section describes handshaking with the processor.

### 15.8.3.1 Software vector mode handshaking

This section describes the software vector mode handshaking.

### 15.8.3.1.1 Acknowledging interrupt request to processor

A timing diagram of the interrupt request and acknowledge handshaking in software vector mode, along with the handshaking near the end of the interrupt exception handler, is shown in [Figure 15-539](#). The INTC examines the peripheral and software-settable interrupt requests. When it finds an asserted peripheral or software-settable interrupt request with a higher priority than PRI in the associated INTC\_CPR<sub>n</sub>, it asserts the interrupt request to the associated processor. The INTVEC field in the associated INTC\_IACKR<sub>n</sub> is updated with the preempting interrupt request's vector when the interrupt request to the processor is asserted. The INTVEC field retains that value until the next time the interrupt request to the processor is asserted. The rest of the handshaking is described in [Software vector mode](#).

### 15.8.3.1.2 End of interrupt exception handler

Before the interrupt exception handling completes, INTC\_EOIR\_PRC<sub>n</sub> must be written. When it is written, the associated LIFO is popped so that the preempted priority is restored into PRI of the associated INTC\_CPR\_PRC<sub>n</sub>. Before it is written, the peripheral or software-settable flag bit must be cleared so that the peripheral or software-settable interrupt request is negated.

#### NOTE

To ensure proper operation across all Power Architecture MCUs, execute an **mbar** or **msync** instruction between the access to clear the flag bit and the write to the INTC\_EOIR\_PRC<sub>n</sub>.

When returning from the preemption, the INTC does not search for the peripheral or software-settable interrupt request whose ISR was preempted. Depending on how much the ISR has progressed, that interrupt request may no longer even be asserted. When PRI in the associated INTC\_CPR\_PRC<sub>n</sub> is lowered to the priority of the preempted ISR, the interrupt request for the preempted ISR or any other asserted peripheral or software-settable interrupt request at or below that priority will not cause a preemption. Instead, after the restoration of the preempted context, the processor will return to the instruction address that it had been going to execute next, before it was preempted. This next instruction is part of the preempted ISR or the interrupt exception handler's prolog or epilog.

**Figure 15-539. Timing diagram of software vector mode handshaking**

### 15.8.3.2 Hardware vector mode handshaking

A timing diagram of the interrupt request and acknowledge handshaking in hardware vector mode, along with the handshaking near the end of the interrupt exception handler, is shown in [Figure 15-540](#). As in software vector mode, the INTC examines the peripheral and software-settable interrupt requests, and when it finds an asserted interrupt request with a higher priority than PRI in the associated INTC\_CPR $n$ , it asserts the interrupt request to the associated processor. The INTVEC field in the associated INTC\_IACKR $n$  is updated with the preempting peripheral or software-settable interrupt request's vector when the interrupt request to the processor is asserted. The INTVEC field retains that value until the next time the interrupt request to the associated processor is asserted. In addition, the value of the interrupt vector to the associated processor matches the value of the INTVEC field in the associated INTC\_IACKR $n$ . The rest of the handshaking is described in [Hardware vector mode](#).

The handshaking near the end of the interrupt exception handler, that is the writing to the associated `INTC_EOIRn`, is the same as in software vector mode. See [End of interrupt exception handler](#).

**Figure 15-540. Timing diagram for hardware vector mode handshaking**

## 15.9 Initialization/application information

This section contains initialization/application information.

### 15.9.1 Initialization flow

After exiting reset, all of the  $PRI_n$  and  $PRC\_SEL_n$  fields in  $INTC\_PSR_n$  are zero, and  $PRI$  in the  $INTC\_CPR_n$  registers is 15d. These reset values prevent the INTC from asserting the interrupt request to the processors. The enable or mask bits in the peripherals are reset such that the peripheral interrupt requests are negated. An initialization sequence for allowing the peripheral and software-settable interrupt requests to cause an interrupt request to the processor is:

- interrupt\_request\_initialization:
  - Configure  $HVEN\_PRC_n$  in  $INTC\_MCR$ .
  - Configure  $VTBA\_PRC_n$  in  $INTC\_IACKR\_PRC_n$ .
  - Raise the  $PRI_n$  fields and set the  $PRC\_SEL_n$  fields to the desired processor in  $INTC\_PSR_n$ .
  - Set the enable bits or clear the mask bits for the peripheral interrupt requests.

- Lower PRI in INTC\_CPR\_PRCn to zero.
- Enable recognition of interrupts by the processor(s).

## 15.9.2 Interrupt exception handler

These example interrupt exception handlers excerpts use Power Architecture assembly code.

### 15.9.2.1 Software vector mode

```

interrupt_exception_handler:
b      interrupt_exception_handler_continued# 16 bytes available, branch to continue

interrupt_exception_handler_continued:
code to create stack frame, save working register, and save SRR0 and SRR1 (Power
Architecture Save/Restore registers) (not shown)

lis      r3,INTC_IACKR_PRCn@ha      # form adjusted upper half of INTC_IACKR_PRCn address
lwz      r3,INTC_IACKR_PRCn@l(r3)   # load INTC_IACKR_PRCn, which clears request to
processor
lwz      r3,0x0(r3)                 # load address of ISR from vector table
wrteei   1                          # enable processor recognition of interrupts

code to save rest of context required by Power Architecture EABI (Embedded Binary
Application Interface) (not shown)

mtlrr    r3                          # move the INTC_IACKRn address into the link register
blrl     # branch to ISR; link register updated with epilog
# address

epilog:
code to restore most of context required by Power Architecture EABI (not shown)
# Popping the LIFO after the restoration of most of the context and the disabling of
processor
# recognition of interrupts eases the calculation of the maximum stack depth at the cost of
# postponing the servicing of the next interrupt request.
mbar     # ensure store to clear flag bit has completed
lis      r3,INTC_EOIR_PRCn@ha      # form adjusted upper half of INTC_EOIR_PRCn address
li       r4,0x0                    # form 0 to write to INTC_EOIR_PRCn
wrteei   0                          # disable processor recognition of interrupts
stw      r4,INTC_EOIR_PRCn@l(r3)   # store to INTC_EOIR_PRCn, informing INTC to lower
priority
code to restore SRR0 and SRR1, restore working registers, and delete stack frame (not shown)

rfi

vector_table_base_address:
address of ISR for interrupt with vector 0
address of ISR for interrupt with vector 1
.
.
.
address of ISR for interrupt with vector 510
address of ISR for interrupt with vector 511
ISRx:
code to service the interrupt event (not shown)
code to clear flag bit which drives interrupt request to INTC (not shown)
blr     # return to epilog

```

### 15.9.2.2 Hardware vector mode

This interrupt exception handler is useful with processor and system bus implementations that support a hardware vector. This example assumes that each

`interrupt_exception_handlerx` only has space for four instructions, and therefore a branch to `interrupt_exception_handler_continuedx` is needed.

```

interrupt_exception_handlerx:
b   interrupt_exception_handler_continuedx# 16 bytes available, branch to continue

interrupt_exception_handler_continuedx:
code to create stack frame, save working register, and save SRR0 and SRR1 (not shown)

wrteei 1      # enable processor recognition of interrupts

code to save rest of context required by Power Architecture EABI (not shown)

bl   ISRx     # branch to ISR for interrupt with vector x

epilog:
code to restore most of context required by Power Architecture EABI (not shown)

# Popping the LIFO after the restoration of most of the context and the disabling of
processor
# recognition of interrupts eases the calculation of the maximum stack depth at the cost of
# postponing the servicing of the next interrupt request.
mbar          # ensure store to clear flag bit has completed
lis   r3,INTC_EOIR_PRCn@ha # form adjusted upper half of INTC_EOIR_PRCn address
li    r4,0x0    # form 0 to write to INTC_EOIR_PRCn
wrteei 0      # disable processor recognition of interrupts
stw   r4,INTC_EOIR_PRCn@l(r3) # store to INTC_EOIR_PRCn, informing INTC to lower priority

code to restore SRR0 and SRR1, restore working registers, and delete stack frame (not shown)

rfi

ISRx:
code to service the interrupt event
code to clear flag bit which drives interrupt request to INTC

blr   # branch to epilog

```

### 15.9.3 ISR, RTOS, and task hierarchy

The RTOS and all of the tasks under its control typically execute with PRI in `INTC_CPRn` having a value of 0. The RTOS will execute the tasks according to whatever priority scheme it may have, but that priority scheme is independent and has a lower priority of execution than the priority scheme of the INTC. In other words, the ISRs execute above `INTC_CPRn` priority 0 and outside the control of the RTOS, the RTOS executes at `INTC_CPRn` priority 0, and while the tasks execute at different priorities under the control of the RTOS, they also execute at `INTC_CPRn` priority 0.

If a task shares a resource with an ISR and the Priority Ceiling Protocol (PCP) is being used to manage that shared resource, then the task's priority can be elevated in the `INTC_CPRn` while the shared resource is being accessed.

An ISR whose `PRIn` in `INTC_PSRn` has a value of 0 will not cause an interrupt request to the selected processor, even if its peripheral or software-settable interrupt request is asserted. For a peripheral interrupt request, not setting its enable bit or disabling the mask bit will cause it to remain negated, which consequently also will not cause an interrupt request to the processor. Since the ISRs are outside the control of the RTOS, this ISR will not run unless called by another ISR or the interrupt exception handler, perhaps after executing another ISR.

### 15.9.4 Order of execution

An ISR with a higher priority can preempt an ISR with a lower priority, regardless of the unique vectors associated with each of their peripheral or software-settable interrupt requests. However, if multiple peripheral or software-settable interrupt requests are asserted, more than one of these interrupt requests has the highest priority and that priority is high enough to cause preemption, the INTC selects the one with the lowest unique vector regardless of the order in time that they asserted. However, the ability to meet deadlines with this scheduling scheme is no less than if the ISRs execute in the time order that their peripheral or software-settable interrupt requests asserted.

The example in the following table shows the order of execution of both cases, ISRs with different priorities and ISRs with the same priority.

**Table 15-534. Order of ISR execution example**

| Step # | Step Description                                                                             | Code executing at end of step |                     |        |        |        |                             | PRI in INTC_CPR at end of step |
|--------|----------------------------------------------------------------------------------------------|-------------------------------|---------------------|--------|--------|--------|-----------------------------|--------------------------------|
|        |                                                                                              | RTOS                          | ISR108 <sub>1</sub> | ISR208 | ISR308 | ISR408 | interrupt exception handler |                                |
| 1      | RTOS at priority 0 is executing.                                                             | X                             |                     |        |        |        |                             | 0                              |
| 2      | Peripheral interrupt request 100 at priority 1 asserts. Interrupt taken.                     |                               | X                   |        |        |        |                             | 1                              |
| 3      | Peripheral interrupt request 400 at priority 4 asserts. Interrupt taken.                     |                               |                     |        |        | X      |                             | 4                              |
| 4      | Peripheral interrupt request 300 at priority 3 asserts.                                      |                               |                     |        |        | X      |                             | 4                              |
| 5      | Peripheral interrupt request 200 at priority 3 asserts.                                      |                               |                     |        |        | X      |                             | 4                              |
| 6      | ISR408 completes. Interrupt exception handler writes to <code>INTC_EOIR<sub>n</sub></code> . |                               |                     |        |        |        | X                           | 1                              |

*Table continues on the next page...*

**Table 15-534. Order of ISR execution example (continued)**

| Step # | Step Description                                                                                        | Code executing at end of step |                     |        |        |        |                             | PRI in INTC_CPR at end of step |
|--------|---------------------------------------------------------------------------------------------------------|-------------------------------|---------------------|--------|--------|--------|-----------------------------|--------------------------------|
|        |                                                                                                         | RTOS                          | ISR108 <sup>1</sup> | ISR208 | ISR308 | ISR408 | interrupt exception handler |                                |
| 7      | Interrupt taken. ISR208 starts to execute, even though peripheral interrupt request 300 asserted first. |                               |                     | X      |        |        |                             | 3                              |
| 8      | ISR208 completes. Interrupt exception handler writes to INTC_EOIR <sub>n</sub> .                        |                               |                     |        |        |        | X                           | 1                              |
| 9      | Interrupt taken. ISR308 starts to execute.                                                              |                               |                     |        | X      |        |                             | 3                              |
| 10     | ISR308 completes. Interrupt exception handler writes to INTC_EOIR <sub>n</sub> .                        |                               |                     |        |        |        | X                           | 1                              |
| 11     | ISR108 completes. Interrupt exception handler writes to INTC_EOIR <sub>n</sub> .                        |                               |                     |        |        |        | X                           | 0                              |
| 12     | RTOS continues execution.                                                                               | X                             |                     |        |        |        |                             | 0                              |

1. ISR108 executes for peripheral interrupt request 100 because the first eight ISRs are for software-settable interrupt requests.

## 15.9.5 Priority ceiling protocol

This section describes the priority ceiling protocol.

### 15.9.5.1 Elevating priority

The PRI field in INTC current priority register (INTC\_CPR<sub>n</sub>) is elevated in the OSEK PCP to the ceiling of all of the priorities of the ISRs that share a resource. This protocol therefore allows coherent accesses of the ISRs to that shared resource.

For example, ISR1 has a priority of 1, ISR2 has a priority of 2, and ISR3 has a priority of 3. They all share the same resource. Before ISR1 or ISR2 can access that resource, they must raise the PRI value in INTC\_CPR<sub>n</sub> to 3, the ceiling of all of the ISR priorities. After they release the resource, they must lower the PRI value in INTC\_CPR<sub>n</sub> to prevent further priority inversion. If they do not raise their priority, then ISR2 can preempt ISR1, and ISR3 can preempt ISR1 or ISR2, possibly corrupting the shared resource. Another possible failure mechanism is deadlock if the higher priority ISR needs the lower priority ISR to release the resource before it can continue, but the lower priority ISR cannot release the resource until the higher priority ISR completes and execution returns to the lower priority ISR.

Using the PCP instead of disabling processor recognition of all interrupts eliminates the time when accessing a shared resource that all higher priority interrupts are blocked. For example, while ISR3 cannot preempt ISR1 while it is accessing the shared resource, all of the ISRs with a priority higher than 3 can preempt ISR1.

### 15.9.5.2 Ensuring coherency

This section discusses how to ensure coherency.

#### 15.9.5.2.1 Interrupt with blocked priority

A scenario can exist that can cause non-coherent accesses to the shared resource. As an example, ISR1 and ISR2 both share a resource. ISR1 has a lower priority than ISR2. ISR1 is executing, and it writes to the `INTC_CPRn`. The instruction following this store is a store to a value in a shared coherent data block. Either just before or at the same time as the first store, the INTC asserts the interrupt request to the processor because the peripheral interrupt request for ISR2 has asserted. As the processor is responding to the interrupt request from the INTC, and as it is aborting transactions and flushing its pipeline, it is possible (in some implementations) that both of these stores are executed. ISR2 thereby assumes that it can access the data block coherently, but the data block has been corrupted.

When the Current Priority Register's (INTC\_CPR\_PCR's) PRI field in the INTC is updated by software, external interrupts from the INTC to the core can be disabled so that an external interrupt will never be taken in the window of time when a system resource (PRI field) is being changed. Disabling interrupts and re-enabling them after the PRI elevation, as well as providing additional core clocks of delay after interrupts have been enabled, provides enough delay for the ISR that has elevated its PRI to be interrupted by a pending ISR before the ISR elevating PRI accesses a shared memory block.

To ensure coherent access to the shared data block, modifications to PRI in INTC\_CPR\_PRCx can be made by services managing shared resources with the following code sequence:

- disable processor recognition of interrupts
- PRI modification (guarded, cache inhibited)
- enable processor recognition of interrupts
- delay 5 core clocks
- coherent data access

The delay of 5 clocks minimum can be achieved by the following series of instructions:

```
or r1, r1, r1
```

```

or r1, r1, r1
or r1, r1, r1
or r1, r1, r1
or r1, r1, r1

```

The `or r1, r1, r1` is not dual issued because the destination of one “or” instruction is the source of the next, hence the instructions cannot be executed in parallel.

### 15.9.5.2.2 Raised priority preserved

The following figure shows the timing diagram for a scenario where a priority that is raised in one ISR is preserved after execution of a pre-empting ISR. The table following the figure explains the events. The example is for software vector mode. Except for the method of retrieving the vector and acknowledging the interrupt request to the processor, hardware vector mode is identical.

**Figure 15-541. Timing diagram of raised priority preserved**

**Table 15-535. Raised priority preserved events**

| Event | Description                                                                                                              |
|-------|--------------------------------------------------------------------------------------------------------------------------|
| A     | Peripheral interrupt request 200 asserts during execution of ISR108 running at priority 1.                               |
| B     | Interrupt request to processor asserts. INTVEC in INTC_IACKRn updates with vector for that peripheral interrupt request. |

*Table continues on the next page...*

**Table 15-535. Raised priority preserved events (continued)**

| Event | Description                                                                                                                                                                                                                                                                                  |
|-------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| C     | ISR108 writes to INTC_CPR <sub>n</sub> to raise priority to 3 before accessing shared coherent data block.                                                                                                                                                                                   |
| D     | PRI in INTC_CPR <sub>n</sub> now at 3, reflecting the write. This write, just before accessing data block, is the last instruction the processor executes before being interrupted.                                                                                                          |
| E     | Interrupt exception handler prolog acknowledges interrupt by reading INTC_IACKR <sub>n</sub> .                                                                                                                                                                                               |
| F     | PRI of 3 pushed onto LIFO. PRI in INTC_CPR <sub>n</sub> updates to 2, the priority of ISR208.                                                                                                                                                                                                |
| G     | ISR208 clears its flag bit, deasserting its peripheral interrupt request.                                                                                                                                                                                                                    |
| H     | Interrupt exception handler epilog writes to INTC_EOIR <sub>n</sub> .                                                                                                                                                                                                                        |
| I     | LIFO pops 3, restoring the raised priority onto PRI in INTC_CPR <sub>n</sub> . Next value to pop from LIFO is the priority from before peripheral interrupt request 100 interrupted. ISR108 now can access data block coherently after interrupt exception handler executes rfi instruction. |

### 15.9.6 Selecting priorities according to request rates and deadlines

The selection of the priorities for the ISRs can be made using Rate Monotonic Scheduling (RMS) or a superset of it, Deadline Monotonic Scheduling (DMS). In RMS, the ISRs which have higher request rates have higher priorities. In DMS, if the deadline is before the next time the ISR is requested, then the ISR is assigned a priority according to the time from the request for the ISR to the deadline, not from the time of the request for the ISR to the next request for it.

For example, ISR1 executes every 100  $\mu$ s, ISR2 executes every 200  $\mu$ s, and ISR3 executes every 300  $\mu$ s. ISR1 has a higher priority than ISR2 which has a higher priority than ISR3. However, if ISR3 has a deadline of 150  $\mu$ s, then it has a higher priority than ISR2.

The INTC supports 16 priorities, which may be many fewer than the number of ISRs. In this case, the ISRs should be grouped with other ISRs that have similar deadlines. For example, a priority could be allocated for every time the request rate doubles. ISRs with request rates around 1 ms would share a priority, ISRs with request rates around 500  $\mu$ s would share a priority, ISRs with request rates around 250  $\mu$ s would share a priority, and so on. With this approach, a range of ISR request rates of  $2^{16}$  could be covered, regardless of the number of ISRs.

Reducing the number of priorities does cause some priority inversion, which reduces the processor's ability to meet its deadlines. However, reducing the number of priorities can reduce the size and latency through the interrupt controller. It also allows easier management of ISRs with similar deadlines that share a resource. They can be placed at the same priority without any further priority inversion, and they do not need to use the PCP to access the shared resource.

## 15.9.7 Software-settable interrupt requests

The software-settable interrupt requests can be used in two ways. They can be used to schedule a lower priority portion of an ISR and for processors to interrupt other processors in a multiple processor system.

### 15.9.7.1 Scheduling a lower priority portion of an ISR

A portion of an ISR needs to be executed at the  $PRI_n$  value in  $INTC\_PSR_n$ , which becomes the  $PRI$  value in  $INTC\_CPR_n$  with the interrupt acknowledge. The ISR, however, can have a portion of it which does not need to be executed at this higher priority. Therefore, executing this later portion which does not need to be executed at this higher priority can prevent the execution of ISRs which do not have a higher priority than the earlier portion of the ISR but do have a higher priority than the later portion of the ISR needs. This preemptive scheduling inefficiency reduces the processor's ability to meet its deadlines.

One option is for the ISR to complete the earlier higher priority portion, but then schedule through the RTOS a task to execute the later lower priority portion. However, some RTOSs can require a large amount of time for an ISR to schedule a task. Therefore, a second option is for the ISR, after completing the higher priority portion, to set a  $SET_n$  bit in  $INTC\_SSCIR_n$ . Writing a '1' to  $SET_n$  causes a software-settable interrupt request. This software-settable interrupt request, which usually will have a lower  $PRI_n$  value in the  $INTC\_PSR_n$ , therefore will not cause preemptive scheduling inefficiencies.

After generating a software settable interrupt request, the higher priority ISR completes. The lower priority ISR is scheduled according to its priority. Execution of the higher priority ISR is not resumed after the completion of the lower priority ISR.

### 15.9.7.2 Scheduling an ISR on another processor

Since the  $SET_n$  bits in the  $INTC\_SSCIR_n$  are memory mapped, processors in multiple processor systems can schedule ISRs on the other processors. One possible application is if one processor simply wants to command another processor to perform a piece of work, and the initiating processor does not need to use the results of that work. If the initiating processor needs to know if the processor executing the software-settable ISR has not completed the work before asking it to again execute that ISR, it can check if the corresponding  $CLR_n$  bit in  $INTC\_SSCIR_n$  is asserted before again writing a 1 to the  $SET_n$  bit.

Another application is the sharing of a block of data. For example, a first processor has completed accessing a block of data and wants a second processor to then access it. Furthermore, after the second processor has completed accessing the block of data, the first processor again wants to access it. The accesses to the block of data must be done coherently. The procedure is that the first processor writes a 1 to a SET $n$  bit on the second processor. The second processor, after accessing the block of data, clears the corresponding CLR $n$  bit and then writes 1 to a SET $n$  bit on the first processor, informing it that it now can access the block of data.

### 15.9.8 Lowering priority within an ISR

In implementations without the software-settable interrupt requests in INTC\_SSCIR $n$ , one way (besides scheduling a task through an RTOS) to prevent preemptive scheduling inefficiencies with an ISR whose work spans multiple priorities (as described in [Scheduling a lower priority portion of an ISR](#)) is to lower the current priority. However, the INTC has a LIFO whose depth is determined by the number of priorities.

#### Note

Lowering the PRI value in INTC\_CPR $n$  within an ISR to below the ISR's corresponding PRI value in INTC\_PSR $n$  allows more preemptions than the depth of the LIFO can support.

Therefore, through its use of the LIFO the INTC does not support lowering the current priority within an ISR as a way to avoid preemptive scheduling inefficiencies.

### 15.9.9 Negating an interrupt request outside of its ISR

This section discusses the negation of an interrupt service request outside of its ISR.

#### 15.9.9.1 Negating an interrupt request as a side effect of an ISR

Some peripherals have flag bits which can be cleared as a side effect of servicing a peripheral interrupt request. For example, reading a specific register can clear the flag bits, and consequently their corresponding interrupt requests too. This clearing as a side effect of servicing a peripheral interrupt request can cause the negation of other peripheral interrupt requests besides the peripheral interrupt request whose ISR presently is executing. This negating of a peripheral interrupt request outside of its ISR can be a desired effect.

### 15.9.9.2 Negating multiple interrupt requests in one ISR

An ISR can clear other flag bits besides its own flag bit. One reason that an ISR clears multiple flag bits is because it serviced those other flag bits, and therefore the ISRs for these other flag bits do not need to be executed.

### 15.9.9.3 Proper setting of interrupt request priority

Whether an interrupt request negates outside of its own ISR due to the side effect of an ISR execution or the intentional clearing of a flag bit, the priorities of the peripheral or software-settable interrupt requests for these other flag bits must be selected properly. Their  $PRI_n$  values in  $INTC\_PSR_n$  must be selected to be at or lower than the priority of the ISR that cleared their flag bits. Otherwise, those flag bits still can cause the interrupt request to the processor to assert. Furthermore, the clearing of these other flag bits also has the same timing relationship to the writing to  $INTC\_SSCIR_n$  as the clearing of the flag bit that caused the present ISR to be executed. Refer to [End of interrupt exception handler](#) for more information.

A flag bit whose enable bit or mask bit is negating its peripheral interrupt request can be cleared at any time, regardless of the peripheral interrupt request's  $PRI_n$  value in  $INTC\_PSR_n$ .

### 15.9.10 Examining LIFO contents

Normally the user does not need to know the contents of the LIFO, or even how deep the LIFO is nested. Although the LIFO contents are not memory-mapped, the user can read the contents by popping the LIFO and reading the  $PRI$  field in the INTC current priority register ( $INTC\_CPR_n$ ). Disabling processor recognition of interrupts while examining the LIFO contents provides a coherent view of the preempted priorities. The code sequence is:

```
pop_lifo:
    store to INTC_EOIR_PRCn
    load INTC_CPR_PRCn, examine PRI, and store onto stack
    if PRI is not zero or value when interrupts were enabled, branch to pop_lifo
```

When the examination is complete, the LIFO can be restored in software vector mode using this code sequence:

```
push_lifo:
    load stacked PRI value and store to INTC_CPR_PRCn
```

```
load INTC_IACKR_PRCn  
if stacked PRI values are not depleted, branch to push_lifo
```

### Note

Reading the INTC\_IACKR\_PRC $n$  acknowledges the interrupt request to the processor and updates the INTC\_CPR\_PRC $n$ [PRI] with the priority of the preempting interrupt request. If the processor recognition of interrupts is disabled during the LIFO restoration, interrupt requests to the processor can go undetected. However, because the peripheral or software-settable interrupt requests are not cleared, the peripheral interrupt request to the processor re-asserts when INTC\_CPR\_PRC $n$ [PRI] is lower than the priorities of those peripheral or software-settable interrupt requests.

## 15.10 Interrupt sources

See [Interrupt vector assignments](#) for the chip-specific list of interrupt sources.

# Chapter 16

## Direct Memory Access Controller (eDMA)

### 16.1 Chip-specific eDMA information

The chip has two instances of the eDMA module: eDMA\_A and eDMA\_B. Each instance supports 64 channels.

See [DMA request mapping](#) for the channel allocation of DMA requests for each module instance.

The eDMA has no direct external MCU signals. However, four external pins can be configured in the SIU to route external eDMA requests to four eDMA\_A channels. See [DMA/Interrupt Request Select Register \(SIU\\_DIRSR\)](#) for details.

### 16.2 Introduction

The enhanced direct memory access (eDMA) controller is a second-generation module capable of performing complex data transfers with minimal intervention from a host processor. The hardware microarchitecture includes:

- A DMA engine that performs:
  - Source address and destination address calculations
  - Data-movement operations
- Local memory containing transfer control descriptors for each of the 64 channels

#### 16.2.1 eDMA system block diagram

[Figure 16-1](#) illustrates the components of the eDMA system, including the eDMA module ("engine").

Figure 16-1. eDMA system block diagram

16.2.2 Block parts

The eDMA module is partitioned into two major modules: the eDMA engine and the transfer-control descriptor local memory.

The eDMA engine is further partitioned into four submodules:

Table 16-1. eDMA engine submodules

| Submodule    | Function                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
|--------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Address path | <p>This block implements registered versions of two channel transfer control descriptors, channel x and channel y, and manages all master bus-address calculations. All the channels provide the same functionality. This structure allows data transfers associated with one channel to be preempted after the completion of a read/write sequence if a higher priority channel activation is asserted while the first channel is active. After a channel is activated, it runs until the minor loop is completed, unless preempted by a higher priority channel. This provides a mechanism (enabled by DCHPRI<sub>n</sub>[ECP]) where a large data move operation can be preempted to minimize the time another channel is blocked from execution.</p> <p>When any channel is selected to execute, the contents of its TCD are read from local memory and loaded into the address path channel x registers for a normal start and into channel y registers for a preemption start. After the minor loop completes execution, the address path hardware writes</p> |

Table continues on the next page...

**Table 16-1. eDMA engine submodules (continued)**

| Submodule                         | Function                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
|-----------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                                   | the new values for the TCDn_{SADDR, DADDR, CITER} back to local memory. If the major iteration count is exhausted, additional processing is performed, including the final address pointer updates, reloading the TCDn_CITER field, and a possible fetch of the next TCDn from memory as part of a scatter/gather operation.                                                                                                                                                                                                                                                                 |
| Data path                         | <p>This block implements the bus master read/write datapath. It includes a data buffer and the necessary multiplex logic to support any required data alignment. The internal read data bus is the primary input, and the internal write data bus is the primary output.</p> <p>The address and data path modules directly support the 2-stage pipelined internal bus. The address path module represents the 1st stage of the bus pipeline (address phase), while the data path module implements the 2nd stage of the pipeline (data phase).</p>                                           |
| Program model/channel arbitration | This block implements the first section of the eDMA programming model as well as the channel arbitration logic. The programming model registers are connected to the internal peripheral bus. The eDMA peripheral request inputs and interrupt request outputs are also connected to this block (via control logic).                                                                                                                                                                                                                                                                         |
| Control                           | This block provides all the control functions for the eDMA engine. For data transfers where the source and destination sizes are equal, the eDMA engine performs a series of source read/destination write operations until the number of bytes specified in the minor loop byte count has moved. For descriptors where the sizes are not equal, multiple accesses of the smaller size data are required for each reference of the larger size. As an example, if the source size references 16-bit data and the destination is 32-bit data, two reads are performed, then one 32-bit write. |

The transfer-control descriptor local memory is further partitioned into:

**Table 16-2. Transfer control descriptor memory**

| Submodule         | Description                                                                                                                                                                                                                                                                                     |
|-------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Memory controller | This logic implements the required dual-ported controller, managing accesses from the eDMA engine as well as references from the internal peripheral bus. As noted earlier, in the event of simultaneous accesses, the eDMA engine is given priority and the peripheral transaction is stalled. |
| Memory array      | TCD storage for each channel's transfer profile.                                                                                                                                                                                                                                                |

### 16.2.3 Features

The eDMA is a highly programmable data-transfer engine optimized to minimize any required intervention from the host processor. It is intended for use in applications where the data size to be transferred is statically known and not defined within the transferred data itself. The eDMA module features:

- All data movement via dual-address transfers: read from source, write to destination
  - Programmable source and destination addresses and transfer size
  - Support for enhanced addressing modes

- 64-channel implementation that performs complex data transfers with minimal intervention from a host processor
  - Internal data buffer, used as temporary storage to support 16- and 32-byte transfers
  - Connections to the crossbar switch for bus mastering the data movement
- Transfer control descriptor (TCD) organized to support two-deep, nested transfer operations
  - 32-byte TCD stored in local memory for each channel
  - An inner data transfer loop defined by a minor byte transfer count
  - An outer data transfer loop defined by a major iteration count
- Channel activation via one of three methods:
  - Explicit software initiation
  - Initiation via a channel-to-channel linking mechanism for continuous transfers
  - Peripheral-paced hardware requests, one per channel
- Fixed-priority and round-robin channel arbitration
- Channel completion reported via programmable interrupt requests
  - One interrupt per channel, which can be asserted at completion of major iteration count
  - Programmable error terminations per channel and logically summed together to form one error interrupt to the interrupt controller
- Programmable support for scatter/gather DMA processing
- Support for complex data structures
- Error detection and error correction

In the discussion of this module,  $n$  is used to reference the channel number.

## 16.3 Modes of operation

The eDMA operates in the following modes:

**Table 16-3. Modes of operation**

| Mode   | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
|--------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Normal | <p>In Normal mode, the eDMA transfers data between a source and a destination. The source and destination can be a memory block or an I/O block capable of operation with the eDMA.</p> <p>A service request initiates a transfer of a specific number of bytes (NBYTES) as specified in the transfer control descriptor (TCD). The minor loop is the sequence of read-write operations that transfers these NBYTES per service request. Each service request executes one iteration of the major loop, which transfers NBYTES of data.</p> |
| Debug  | <p>DMA operation is configurable in Debug mode via the control register:</p> <ul style="list-style-type: none"> <li>• If CR[EDBG] is cleared, the DMA continues to operate.</li> <li>• If CR[EDBG] is set, the eDMA stops transferring data. If Debug mode is entered while a channel is active, the eDMA continues operation until the channel retires.</li> </ul>                                                                                                                                                                         |
| Wait   | Before entering Wait mode, the DMA attempts to complete its current transfer. After the transfer completes, the device enters Wait mode.                                                                                                                                                                                                                                                                                                                                                                                                    |

## 16.4 Memory map/register definition

The eDMA's programming model is partitioned into two regions:

- The first region defines a number of registers providing control functions
- The second region corresponds to the local transfer control descriptor (TCD) memory

### 16.4.1 TCD memory

Each channel requires a 32-byte transfer control descriptor for defining the desired data movement operation. The channel descriptors are stored in the local memory in sequential order: channel 0, channel 1, ... channel 63. Each TCD<sub>*n*</sub> definition is presented as 11 registers of 16 or 32 bits.

Some registers are implemented as two 32-bit registers, and include an H and L suffix, signaling the high and low portions of the control function. This table provides a 32-bit view of the eDMA's memory map.

## 16.4.2 TCD initialization

The initialization of the TCD memory is performed by the eDMA controller after reset. The initialization runs for 256 eDMA clock cycles. All fields in the TCD memory are initialized to 0. All application read or write accesses to the TCD are delayed until the initialization is finished. Prior to activating a channel, you must initialize its TCD with the appropriate transfer profile.

## 16.4.3 TCD structure

### DMA Basics: TCD Structure

- One DMA engine has a number of channels to react to DMA requests
- Each channel has its own TCD

| Word<br>Offset | 0                   | 1                     | 2                            | 3 | 4     | 5 | 6 | 7     | 8    | 9 | 10 | 11 | 12    | 13 | 14 | 15   | 16   | 17           | 18 | 19 | 20 | 21 | 22                  | 23   | 24     | 25           | 26   | 27    | 28       | 29      | 30    | 31 |

<sup>1</sup> The fields implemented in Word 2 depend on whether EDMA\_CR[EMLM] bit is set to 0 or 1.

## 16.4.4 Reserved memory and bit fields

- Reading reserved bits in a register returns the value of zero.

- Writes to reserved bits in a register are ignored.
- Reading or writing a reserved memory location generates a bus error.

## DMA memory map

| Address offset (hex) | Register name                                    | Width (in bits) | Access                | Reset value | Section/ page               |

**16.4.5 Control Register (DMA\_CR)**

The CR defines the basic operating configuration of the DMA. The DMA arbitrates channel service requests in four groups of 16 channels each:

- Group 3 contains channels 63-48
- Group 2 contains channels 47-32
- Group 1 contains channels 31-16
- Group 0 contains channels 15-0

Arbitration within a group can be configured to use either a fixed-priority or a round-robin scheme. For fixed-priority arbitration, the highest priority channel requesting service is selected to execute. The channel priority registers assign the priorities; see the DCHPRIn registers. For round-robin arbitration, the channel priorities are ignored and channels within each group are cycled through (from high to low channel number) without regard to priority.

**NOTE**

For correct operation, writes to the CR register must be performed only when the DMA channels are inactive; that is, when TCDn\_CSR[ACTIVE] bits are cleared.

The group priorities operate in a similar fashion. In group fixed priority arbitration mode, channel service requests in the highest priority group are executed first, where priority level 3 is the highest and priority level 0 is the lowest. The group priorities are assigned

in the GRPnPRI fields of the DMA Control Register (CR). All group priorities must have unique values prior to any channel service requests occurring; otherwise, a configuration error will be reported. For group round robin arbitration, the group priorities are ignored and the groups are cycled through (from high to low group number) without regard to priority.

Minor loop offsets are address offset values added to the final source address (TCDn\_SADDR) or destination address (TCDn\_DADDR) upon minor loop completion. When minor loop offsets are enabled, the minor loop offset (MLOFF) is added to the final source address (TCDn\_SADDR), to the final destination address (TCDn\_DADDR), or to both prior to the addresses being written back into the TCD. If the major loop is complete, the minor loop offset is ignored and the major loop address offsets (TCDn\_SLAST and TCDn\_DLAST\_SGA) are used to compute the next TCDn\_SADDR and TCDn\_DADDR values.

When minor loop mapping is enabled (EMLM is 1), TCDn word2 is redefined. A portion of TCDn word2 is used to specify multiple fields: a source enable bit (SMLOE) to specify the minor loop offset should be applied to the source address (TCDn\_SADDR) upon minor loop completion, a destination enable bit (DMLOE) to specify the minor loop offset should be applied to the destination address (TCDn\_DADDR) upon minor loop completion, and the sign extended minor loop offset value (MLOFF). The same offset value (MLOFF) is used for both source and destination minor loop offsets. When either minor loop offset is enabled (SMLOE set or DMLOE set), the NBYTES field is reduced to 10 bits. When both minor loop offsets are disabled (SMLOE cleared and DMLOE cleared), the NBYTES field is a 30-bit vector.

When minor loop mapping is disabled (EMLM is 0), all 32 bits of TCDn word2 are assigned to the NBYTES field.

Address: 0h base + 0h offset = 0h

| 0–13<br>Reserved | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| 14<br>CX         | Cancel Transfer<br><br>0 Normal operation<br>1 Cancel the remaining data transfer. Stop the executing channel and force the minor loop to finish. The cancel takes effect after the last write of the current read/write sequence. The CX bit clears itself after the cancel has been honored. This cancel retires the channel normally as if the minor loop was completed.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 15<br>ECX        | Error Cancel Transfer<br><br>0 Normal operation<br>1 Cancel the remaining data transfer in the same fashion as the CX bit. Stop the executing channel and force the minor loop to finish. The cancel takes effect after the last write of the current read/write sequence. The ECX bit clears itself after the cancel is honored. In addition to cancelling the transfer, ECX treats the cancel as an error condition, thus updating the Error Status register (DMAx_ES) and generating an optional error interrupt.                                                                                                                                                                                                                                                                                                                                                            |

| 24<br>EMLM       | Enable Minor Loop Mapping<br><br>0 Disabled. TCDn.word2 is defined as a 32-bit NBYTES field.<br>1 Enabled. TCDn.word2 is redefined to include individual enable fields, an offset field, and the NBYTES field. The individual enable fields allow the minor loop offset to be applied to the source address, the destination address, or both. The NBYTES field is reduced when either offset is enabled.                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| 25<br>CLM        | Continuous Link Mode<br><br><b>NOTE:</b> Do not use continuous link mode with a channel linking to itself if there is only one minor loop iteration per service request, e.g., if the channel's NBYTES value is the same as either the source or destination size. The same data transfer profile can be achieved by simply increasing the NBYTES value, which provides more efficient, faster processing.<br><br>0 A minor loop channel link made to itself goes through channel arbitration before being activated again.<br>1 A minor loop channel link made to itself does not go through channel arbitration before being activated again. Upon minor loop completion, the channel activates again if that channel has a minor loop channel link enabled and the link channel is itself. This effectively applies the minor loop offsets and restarts the next minor loop. |
| 26<br>HALT       | Halt DMA Operations                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |

**16.4.6 Error Status Register (DMA\_ES)**

The ES provides information concerning the last recorded channel error. Channel errors can be caused by:

- A configuration error, that is:
  - An illegal setting in the transfer-control descriptor, or
  - An illegal priority register setting in fixed-arbitration
- An error termination to a bus master read or write cycle
- The UCE bit shows an uncorrectable error occurred while the device has ECC protection on the TCD SRAM
- A cancel transfer with error bit that will be set when a transfer is canceled via the corresponding cancel transfer control bit

See [Fault reporting and handling](#) for more details.

Address: 0h base + 4h offset = 4h

### 16.4.7 Enable Request Register High (DMA\_ERQH)

The ERQ{H,L} registers provide a bit map for the 64 channels to enable the request signal for each channel. ERQH supports channels 63-32, while ERQL covers channels 31-00. The state of any given channel enable is directly affected by writes to this register; it is also affected by writes to the SERQ and CERQ. The {S,C}ERQ registers are provided so the request enable for a single channel can easily be modified without needing to perform a read-modify-write sequence to the ERQ{H,L}.

DMA request input signals and this enable request flag must be asserted before a channel's hardware service request is accepted. The state of the eDMA enable request flag does not affect a channel service request made explicitly through software or a linked channel request.

#### NOTE

Disable a channel's hardware service request at the source before clearing the channel's ERQ bit.

Address: 0h base + 8h offset = 8h

**16.4.8 Enable Request Register Low (DMA\_ERQL)**

The ERQ{H,L} registers provide a bit map for the 64 channels to enable the request signal for each channel. ERQH supports channels 63-32, while ERQL covers channels 31-00. The state of any given channel enable is directly affected by writes to this register; it is also affected by writes to the SERQ and CERQ registers. These registers are provided so the request enable for a single channel can easily be modified without needing to perform a read-modify-write sequence to the ERQ{H,L}.

DMA request input signals and this enable request flag must be asserted before a channel's hardware service request is accepted. The state of the DMA enable request flag does not affect a channel service request made explicitly through software or a linked channel request.

**NOTE**

Disable a channel's hardware service request at the source before clearing the channel's ERQ bit.

Address: 0h base + Ch offset = Ch

## 16.4.9 Enable Error Interrupt Register High (DMA\_EEIH)

The EEI{H,L} registers provide a bit map for the 64 channels to enable the error interrupt signal for each channel. EEIH supports channels 63-32, while EEIL covers channels 31-00. The state of any given channel's error interrupt enable is directly affected by writes to this register; it is also affected by writes to the SEEI and CEEI. The {S,C}EEI are provided so the error interrupt enable for a single channel can easily be modified without the need to perform a read-modify-write sequence to the EEI{H,L} registers.

The DMA error indicator and the error interrupt enable flag must be asserted before an error interrupt request for a given channel is asserted to the interrupt controller.

Address: 0h base + 10h offset = 10h

**16.4.10 Enable Error Interrupt Register Low (DMA\_EEIL)**

The EEIL register provides a bit map for the 64 channels to enable the error interrupt signal for each channel. EEIH supports channels 63-32, while EEIL covers channels 31-00. The state of any given channel's error interrupt enable is directly affected by writes to this register; it is also affected by writes to the SEEI and CEEI. These registers are provided so that the error interrupt enable for a single channel can easily be modified without the need to perform a read-modify-write sequence to the EEIH and EEIL registers.

The DMA error indicator and the error interrupt enable flag must be asserted before an error interrupt request for a given channel is asserted to the interrupt controller.

### 16.4.11 Set Enable Request Register (DMA\_SERQ)

The SERQ provides a simple memory-mapped mechanism to set a given bit in the ERQ {H,L} to enable the DMA request for a given channel. The data value on a register write causes the corresponding bit in the ERQ {H,L} to be set. Setting the SAER bit provides a global set function, forcing the entire contents of ERQ {H,L} to be set. If the NOP bit is set, the command is ignored. This allows you to write multiple-byte registers as a 32-bit word. Reads of this register return all zeroes.

Address: 0h base + 18h offset = 18h

|       |     |      |      |   |   |   |   |   |
|-------|-----|------|------|---|---|---|---|---|
| Bit   | 0   | 1    | 2    | 3 | 4 | 5 | 6 | 7 |
| Read  | 0   | 0    | 0    |   |   |   |   |   |
| Write | NOP | SAER | SERQ |   |   |   |   |   |
| Reset | 0   | 0    | 0    | 0 | 0 | 0 | 0 | 0 |

**DMA\_SERQ field descriptions**

| Field       | Description                                                                                                            |
|-------------|------------------------------------------------------------------------------------------------------------------------|

| 2–7<br>SERQ | Set Enable Request<br><br>Sets the corresponding bit in ERQ{H,L}.                                                      |

### 16.4.12 Clear Enable Request Register (DMA\_CERQ)

The CERQ provides a simple memory-mapped mechanism to clear a given bit in the ERQ {H,L} to disable the DMA request for a given channel. The data value on a register write causes the corresponding bit in the ERQ {H,L} to be cleared. Setting the CAER bit provides a global clear function, forcing the entire contents of the ERQ {H,L} to be cleared, disabling all DMA request inputs. If NOP is set, the command is ignored. This allows you to write multiple-byte registers as a 32-bit word. Reads of this register return all zeroes.

NOTE

Disable a channel’s hardware service request at the source before clearing the channel’s ERQ bit.

Address: 0h base + 19h offset = 19h

|       |     |      |      |   |   |   |   |   |
|-------|-----|------|------|---|---|---|---|---|
| Bit   | 0   | 1    | 2    | 3 | 4 | 5 | 6 | 7 |

16.4.13 Set Enable Error Interrupt Register (DMA\_SEEI)

The SEEI provides a simple memory-mapped mechanism to set a given bit in the EEI {H,L} to enable the error interrupt for a given channel. The data value on a register write causes the corresponding bit in the EEI {H,L} to be set. Setting the SAEE bit provides a global set function, forcing the entire EEI {H,L} contents to be set. If the NOP bit is set, the command is ignored. This allows you to write multiple-byte registers as a 32-bit word. Reads of this register return all zeroes.

Address: 0h base + 1Ah offset = 1Ah

|       |     |      |      |   |   |   |   |   |
|-------|-----|------|------|---|---|---|---|---|
| Bit   | 0   | 1    | 2    | 3 | 4 | 5 | 6 | 7 |
| Read  | 0   | 0    | 0    |   |   |   |   |   |
| Write | NOP | SAEE | SEEI |   |   |   |   |   |
| Reset | 0   | 0    | 0    | 0 | 0 | 0 | 0 | 0 |

**16.4.14 Clear Enable Error Interrupt Register (DMA\_CEEI)**

The CEEI provides a simple memory-mapped mechanism to clear a given bit in the EEI {H,L} to disable the error interrupt for a given channel. The data value on a register write causes the corresponding bit in the EEI {H,L} to be cleared. Setting the CAEE bit provides a global clear function, forcing the EEI {H,L} contents to be cleared, disabling all DMA request inputs. If the NOP bit is set, the command is ignored. This allows you to write multiple-byte registers as a 32-bit word. Reads of this register return all zeroes.

Address: 0h base + 1Bh offset = 1Bh

16.4.15 Clear Interrupt Request Register (DMA\_CINT)

The CINT provides a simple, memory-mapped mechanism to clear a given bit in the INT {H,L} to disable the interrupt request for a given channel. The given value on a register write causes the corresponding bit in the INT {H,L} to be cleared. Setting the CAIR bit provides a global clear function, forcing the entire contents of the INT {H,L} to be cleared, disabling all DMA interrupt requests. If the NOP bit is set, the command is ignored. This allows you to write multiple-byte registers as a 32-bit word. Reads of this register return all zeroes.

Address: 0h base + 1Ch offset = 1Ch

### 16.4.16 Clear Error Register (DMA\_CERR)

The CERR provides a simple memory-mapped mechanism to clear a given bit in the ERR {H,L} to disable the error condition flag for a given channel. The given value on a register write causes the corresponding bit in the ERR {H,L} to be cleared. Setting the CAEI bit provides a global clear function, forcing the ERR {H,L} contents to be cleared, clearing all channel error indicators. If the NOP bit is set, the command is ignored. This allows you to write multiple-byte registers as a 32-bit word. Reads of this register return all zeroes.

Address: 0h base + 1Dh offset = 1Dh

|       |     |      |      |   |   |   |   |   |
|-------|-----|------|------|---|---|---|---|---|
| Bit   | 0   | 1    | 2    | 3 | 4 | 5 | 6 | 7 |
| Read  | 0   | 0    | 0    |   |   |   |   |   |
| Write | NOP | CAEI | CERR |   |   |   |   |   |
| Reset | 0   | 0    | 0    | 0 | 0 | 0 | 0 | 0 |

DMA\_CERR field descriptions

| Field       | Description                                                                                                               |
|-------------|---------------------------------------------------------------------------------------------------------------------------|
| 0<br>NOP    | No Op enable<br>0 Normal operation<br>1 No operation, ignore the other bits in this register                              |

| 2–7<br>CERR | Clear Error Indicator<br>Clears the corresponding bit in ERR {H,L}                                                        |

16.4.17 Set START Bit Register (DMA\_SSRT)

The SSRT provides a simple memory-mapped mechanism to set the START bit in the TCD of the given channel. The data value on a register write causes the START bit in the corresponding transfer control descriptor to be set. Setting the SAST bit provides a global set function, forcing all START bits to be set. If the NOP bit is set, the command is ignored. This allows you to write multiple-byte registers as a 32-bit word. Reads of this register return all zeroes.

Address: 0h base + 1Eh offset = 1Eh

|       |     |      |      |   |   |   |   |   |
|-------|-----|------|------|---|---|---|---|---|
| Bit   | 0   | 1    | 2    | 3 | 4 | 5 | 6 | 7 |
| Read  | 0   | 0    | 0    |   |   |   |   |   |
| Write | NOP | SAST | SSRT |   |   |   |   |   |
| Reset | 0   | 0    | 0    | 0 | 0 | 0 | 0 | 0 |

### 16.4.18 Clear DONE Status Bit Register (DMA\_CDNE)

The CDNE provides a simple memory-mapped mechanism to clear the DONE bit in the TCD of the given channel. The data value on a register write causes the DONE bit in the corresponding transfer control descriptor to be cleared. Setting the CADN bit provides a global clear function, forcing all DONE bits to be cleared. If the NOP bit is set, the command is ignored. This allows you to write multiple-byte registers as a 32-bit word. Reads of this register return all zeroes.

Address: 0h base + 1Fh offset = 1Fh

### 16.4.19 Interrupt Request Register High (DMA\_INTH)

The INT{H,L} provide a bit map for the 64 channels signaling the presence of an interrupt request for each channel. Depending on the appropriate bit setting in the transfer-control descriptions, the eDMA engine generates an interrupt on a data transfer completion. The outputs of this register are directly routed to the interrupt controller. During the interrupt-service routine associated with any given channel, the software must clear the appropriate bit, negating the interrupt request. Typically, a write to the CINT register in the interrupt service routine is used for this purpose.

## Memory map/register definition

The state of any given channel's interrupt request is directly affected by writes to this register; it is also affected by writes to the CINT register. On writes to INT, a 1 in any bit position clears the corresponding channel's interrupt request. A zero in any bit position has no affect on the corresponding channel's current interrupt status. The CINT register is provided so the interrupt request for a single channel can easily be cleared without the need to perform a read-modify-write sequence to the INT{H,L} register.

**16.4.20 Interrupt Request Register Low (DMA\_INTL)**

The INT {H,L} register provides a bit map for the 64 channels signaling the presence of an interrupt request for each channel. Depending on the appropriate bit setting in the transfer-control descriptors, the eDMA engine generates an interrupt on data transfer completion. The outputs of this register are directly routed to the interrupt controller. During the interrupt-service routine associated with any given channel, it is the software's responsibility to clear the appropriate bit, negating the interrupt request. Typically, a write to the CINT register in the interrupt service routine is used for this purpose.

The state of any given channel's interrupt request is directly affected by writes to this register; it is also affected by writes to the CINT register. On writes to INT, a 1 in any bit position clears the corresponding channel's interrupt request. A zero in any bit position has no affect on the corresponding channel's current interrupt status. The CINT register is provided so the interrupt request for a single channel can easily be cleared without the need to perform a read-modify-write sequence to the INT {H,L} register.

### 16.4.21 Error Register High (DMA\_ERRH)

The ERR{H,L} provide a bit map for the 64 channels, signaling the presence of an error for each channel. ERRH supports channels 63-32, while ERRL covers channels 31-00. The eDMA engine signals the occurrence of a error condition by setting the appropriate bit in this register. The outputs of this register are enabled by the contents of EEI, then logically summed across groups of 16, 32 and 64 channels to form several group error interrupt requests. These are then routed to the interrupt controller. During the execution of the interrupt-service routine associated with any DMA errors, the software must clear the appropriate bit, negating the error-interrupt request. Typically, a write to CERR in the interrupt-service routine is used for this purpose. The normal DMA channel completion indicators, setting the transfer control descriptor DONE flag and the possible assertion of an interrupt request, are not affected when an error is detected.

The contents of this register can also be polled, because a non-zero value indicates the presence of a channel error regardless of the state of EEI. The state of any given channel's error indicators is affected by writes to this register; it is also affected by writes to CERR. On writes to ERR, a one in any bit position clears the corresponding channel's error status. A zero in any bit position has no affect on the corresponding channel's current error status. CERR is provided so the error indicator for a single channel can easily be cleared.

### 16.4.22 Error Register Low (DMA\_ERRL)

The ERR {H,L} provides a bit map for the 64 channels, signaling the presence of an error for each channel. ERRH supports channels 63-32, while ERRL covers channels 31-00. The eDMA engine signals the occurrence of an error condition by setting the appropriate bit in this register. The outputs of this register are enabled by the contents of the EEI, then logically summed across groups of 16, 32 and 64 channels to form several group error interrupt requests, which are then routed to the interrupt controller. During the execution of the interrupt-service routine associated with any DMA errors, it is software's responsibility to clear the appropriate bit, negating the error-interrupt request. Typically, a write to the CERR in the interrupt-service routine is used for this purpose. The normal DMA channel completion indicators (setting the transfer control descriptor DONE flag and the possible assertion of an interrupt request) are not affected when an error is detected.

The contents of this register can also be polled because a non-zero value indicates the presence of a channel error regardless of the state of the EEI. The state of any given channel's error indicators is affected by writes to this register; it is also affected by writes to the CERR. On writes to the ERR, a one in any bit position clears the corresponding channel's error status. A zero in any bit position has no affect on the corresponding channel's current error status. The CERR is provided so the error indicator for a single channel can easily be cleared.

**16.4.23 Hardware Request Status Register High (DMA\_HRSH)**

The HRS{H,L} provide a bit map for the DMA channels, signaling the presence of a hardware request for each channel. HRSH supports channels 63-32, while HRSL covers channels 31-0. The hardware request status bits reflect the current state of the register and DMA request signals, qualified via the ERQ{H,L} fields, as seen by the DMA's arbitration logic. This view into the hardware request signals may be used for debug purposes.

**NOTE**

These bits reflect the state of the request as seen by the arbitration logic. Therefore, this status is affected by the ERQ {H,L} bits.

The HRS bit for its respective channel remains asserted for the period when a Hardware Request is Present on the Channel. After the Request is completed and Channel is free, the HRS bit is automatically cleared by hardware.

Address: 0h base + 30h offset = 30h

**16.4.24 Hardware Request Status Register Low (DMA\_HRSL)**

The HRS{H,L} registers provide a bit map for the DMA channels, signaling the presence of a hardware request for each channel. HRSH supports channels 63-32, while HRSL covers channels 31-0. The hardware request status bits reflect the current state of the register and qualified (via the ERQ {H,L} fields) DMA request signals as seen by the DMA's arbitration logic. This view into the hardware request signals may be used for debug purposes.

**NOTE**

These bits reflect the state of the request as seen by the arbitration logic. Therefore, this status is affected by the ERQ {H,L} bits.

The HRS bit for its respective channel remains asserted for the period when a Hardware Request is Present on the Channel. After the Request is completed and Channel is free, the HRS bit is automatically cleared by hardware.

Address: 0h base + 34h offset = 34h

**16.4.25 Global PCU Output Register (DMA\_GPOR<sub>n</sub>)**

The DMAGPORH and DMAGPORL registers provides coherency information to the Peripheral Coherency Unit (PCU). The DMAGPORH and DMAGPORL registers use a bit map for the implemented channels {16,32,64} to enable a global write signal to the PCU on a per channel basis. When the bit in the corresponding channel is set, the eDMA will signal the PCU whenever that channel is performing a write. The DMAGPORH and DMAGPORL registers perform no functions within the eDMA.

**NOTE**

See the PCU chapter for coherency information and global write usage.

### 16.4.26 Channel n Priority Register (DMA\_DCHPRIn)

When fixed-priority channel arbitration is enabled ( $CR[ERCA] = 0$ ), the contents of these registers define the unique priorities associated with each channel within a group. The channel priorities are evaluated by numeric value; for example, 0 is the lowest priority, 1 is the next higher priority, then 2, 3, etc. Software must program the channel priorities with unique values; otherwise, a configuration error is reported. The range of the priority value is limited to the values of 0 through 15. When read, the GRPPRI bits of the DCHPRIn register reflect the current priority level of the group of channels in which the corresponding channel resides. GRPPRI bits are not affected by writes to the DCHPRIn registers. The group priority is assigned in the DMA control register.

Address:  $0h \text{ base} + 100h \text{ offset} + (1d \times i)$ , where  $i=0d$  to  $63d$

|--------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–4<br>SMOD  | Source Address Modulo<br><br>0 Source address modulo feature is disabled<br>≠0 This value defines a specific address range specified to be the value after SADDR + SOFF calculation is performed on the original register value. Setting this field provides the ability to implement a circular data queue easily. For data queues requiring power-of-2 size bytes, the queue should start at a 0-modulo-size address and the SMOD field should be set to the appropriate value for the queue, freezing the desired number of upper address bits. The value programmed into this field specifies the number of lower address bits allowed to change. For a circular queue application, the SOFF is typically set to the transfer size to implement post-increment addressing with the SMOD function constraining the addresses to a 0-modulo-size range. |
| 5–7<br>SSIZE | Source data transfer size<br><br><b>NOTE:</b> Using a Reserved value causes a configuration error.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |

**16.4.30 TCD Minor Byte Count (Minor Loop Mapping Disabled) (DMA\_TCDn\_NBYTES\_MLNO)**

This register, or one of the next two registers (TCD\_NBYTES\_MLOFFNO, TCD\_NBYTES\_MLOFFYES), defines the number of bytes to transfer per request. Which register to use depends on whether minor loop mapping is disabled, enabled but not used for this channel, or enabled and used.

TCD word 2 is defined as follows if:

- Minor loop mapping is disabled (CR[EMLM] = 0)

If minor loop mapping is enabled, see the TCD\_NBYTES\_MLOFFNO and TCD\_NBYTES\_MLOFFYES register descriptions for the definition of TCD word 2.

Address: 0h base + 1008h offset + (32d × i), where i=0d to 63d

| Field          | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
|----------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–31<br>NBYTES | <p>Minor Byte Transfer Count</p> <p>Number of bytes to be transferred in each service request of the channel. As a channel activates, the appropriate TCD contents load into the eDMA engine, and the appropriate reads and writes perform until the minor byte transfer count has transferred. This is an indivisible operation and cannot be halted. It can, however, be stalled by using the bandwidth control field, or via preemption. After the minor count is exhausted, the SADDR and DADDR values are written back into the TCD memory, the major iteration count is decremented and restored to the TCD memory. If the major iteration count is completed, additional processing is performed.</p> <p><b>NOTE:</b> An NBYTES value of 0x0000_0000 is interpreted as a 4 GB transfer.</p> |

### 16.4.31 TCD Signed Minor Loop Offset (Minor Loop Mapping Enabled and Offset Disabled) (DMA\_TCDn\_NBYTES\_MLOFFNO)

One of three registers (this register, TCD\_NBYTES\_MLNO, or TCD\_NBYTES\_MLOFFYES), defines the number of bytes to transfer per request. Which register to use depends on whether minor loop mapping is disabled, enabled but not used for this channel, or enabled and used.

TCD word 2 is defined as follows if:

- Minor loop mapping is enabled (CR[EMLM] = 1) and
- SMLOE = 0 and DMLOE = 0

If minor loop mapping is enabled and SMLOE or DMLOE is set, then refer to the TCD\_NBYTES\_MLOFFYES register description. If minor loop mapping is disabled, then refer to the TCD\_NBYTES\_MLNO register description.

Address: 0h base + 1008h offset + (32d × i), where i=0d to 63d

### 16.4.32 TCD Signed Minor Loop Offset (Minor Loop Mapping and Offset Enabled) (DMA\_TCDn\_NBYTES\_MLOFFYES)

One of three registers (this register, TCD\_NBYTES\_MLNO, or TCD\_NBYTES\_MLOFFNO), defines the number of bytes to transfer per request. Which register to use depends on whether minor loop mapping is disabled, enabled but not used for this channel, or enabled and used.

TCD word 2 is defined as follows if:

- Minor loop mapping is enabled (CR[EMLM] = 1) and
- Minor loop offset is enabled (SMLOE or DMLOE = 1)

If minor loop mapping is enabled and SMLOE and DMLOE are cleared, then refer to the TCD\_NBYTES\_MLOFFNO register description. If minor loop mapping is disabled, then refer to the TCD\_NBYTES\_MLNO register description.

| 2–21<br>MLOFF   | If SMLOE or DMLOE is set, this field represents a sign-extended offset applied to the source or destination address to form the next-state value after the minor loop completes.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| 22–31<br>NBYTES | Minor Byte Transfer Count<br><br>Number of bytes to be transferred in each service request of the channel.<br><br>As a channel activates, the appropriate TCD contents load into the eDMA engine, and the appropriate reads and writes perform until the minor byte transfer count has transferred. This is an indivisible operation and cannot be halted. It can, however, be stalled by using the bandwidth control field, or via preemption. After the minor count is exhausted, the SADDR and DADDR values are written back into the TCD memory, the major iteration count is decremented and restored to the TCD memory. If the major iteration count is completed, additional processing is performed. |

## 16.4.33 TCD Last Source Address Adjustment (DMA\_TCDn\_SLAST)

Address: 0h base + 100Ch offset + (32d × i), where i=0d to 63d

## DMA\_TCDn\_CSR field descriptions

| Field      | Description                                                                                                                                                                                                                                                                                                                                                                          |
|------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–1<br>BWC | <p>Bandwidth Control</p> <p>Throttles the amount of bus bandwidth consumed by the eDMA. Generally, as the eDMA processes the minor loop, it continuously generates read/write sequences until the minor count is exhausted. This field forces the eDMA to stall after the completion of each read/write access to control the bus request bandwidth seen by the crossbar switch.</p> |

The eDMA hardware automatically clears this flag after the channel begins execution.</p> <p>0 The channel is not explicitly started.<br/> 1 The channel is explicitly started via a software initiated service request.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

## 16.5 Functional description

The operation of the eDMA is described in the following subsections.

### 16.5.1 eDMA basic data flow

The basic flow of a data transfer can be partitioned into three segments.

As shown in the following diagram, the first segment involves the channel activation:

**Figure 16-1065. eDMA operation, part 1**

This example uses the assertion of the eDMA peripheral request signal to request service for channel  $n$ . Channel activation via software and the  $\text{TCD}_n\text{-CSR}[\text{START}]$  bit follows the same basic flow as peripheral requests. The eDMA request input signal is registered internally and then routed through the eDMA engine: first through the control module, then into the program model and channel arbitration. In the next cycle, the channel arbitration performs, using the fixed-priority or round-robin algorithm. After arbitration is complete, the activated channel number is sent through the address path and converted into the required address to access the local memory for  $\text{TCD}_n$ . Next, the TCD memory is accessed and the required descriptor read from the local memory and loaded into the eDMA engine address path channel  $x$  or  $y$  registers. The TCD memory is 64 bits wide to minimize the time needed to fetch the activated channel descriptor and load it into the address path channel  $x$  or  $y$  registers.

The following diagram illustrates the second part of the basic data flow:

**Figure 16-1066. eDMA operation, part 2**

The modules associated with the data transfer (address path, data path, and control) sequence through the required source reads and destination writes to perform the actual data movement. The source reads are initiated and the fetched data is temporarily stored in the data path block until it is gated onto the internal bus during the destination write. This source read/destination write processing continues until the minor byte count has transferred.

After the minor byte count has moved, the final phase of the basic data flow is performed. In this segment, the address path logic performs the required updates to certain fields in the appropriate TCD, for example, SADDR, DADDR, CITER. If the major iteration count is exhausted, additional operations are performed. These include the final address adjustments and reloading of the BITER field into the CITER. Assertion of an optional interrupt request also occurs at this time, as does a possible fetch of a new TCD from memory using the scatter/gather address pointer included in the descriptor (if scatter/gather is enabled). The updates to the TCD memory and the assertion of an interrupt request are shown in the following diagram.

Figure 16-1067. eDMA operation, part 3

### 16.5.2 Fault reporting and handling

Channel errors are reported in the Error Status register (DMAx\_ES) and can be caused by:

- A configuration error, which is an illegal setting in the transfer-control descriptor or an illegal priority register setting in Fixed-Arbitration mode
- An uncorrectable ECC error, or
- An error termination to a bus master read or write cycle

A configuration error is reported when the starting source or destination address, source or destination offsets, minor loop byte count, or the transfer size represent an inconsistent state. Each of these possible causes are detailed below:

- The addresses and offsets must be aligned on 0-modulo-transfer-size boundaries.

- The minor loop byte count must be a multiple of the source and destination transfer sizes.
- All source reads and destination writes must be configured to the natural boundary of the programmed transfer size respectively.
- In fixed arbitration mode, a configuration error is caused by any two channel priorities being equal within a group, or any group priority levels being equal among the groups. All channel priority levels within a group must be unique and all group priority levels among the groups must be unique when fixed arbitration mode is enabled.

### **NOTE**

When two channels have the same priority, a channel priority error exists and will be reported in the Error Status register. However, the channel number will not be reported in the Error Status register. When all of the channel priorities within a group are not unique, the channel number selected by arbitration is undetermined.

To aid in Channel Priority Error (CPE) debug, set the Halt On Error bit in the DMA's Control Register. If all of the channel priorities within a group are not unique, the DMA will be halted after the CPE error is recorded. The DMA will remain halted and will not process any channel service requests. Once all of the channel priorities are set to unique numbers, the DMA may be enabled again by clearing the Halt bit.

- If a scatter/gather operation is enabled upon channel completion, a configuration error is reported if the scatter/gather address (DLAST\_SGA) is not aligned on a 32-byte boundary.
- If minor loop channel linking is enabled upon channel completion, a configuration error is reported when the link is attempted if the TCDn\_CITER[E\_LINK] bit does not equal the TCDn\_BITER[E\_LINK] bit.

If enabled, all configuration error conditions, except the scatter/gather and minor-loop link errors, report as the channel activates and asserts an error interrupt request. A scatter/gather configuration error is reported when the scatter/gather operation begins at major loop completion when properly enabled. A minor loop channel link configuration error is reported when the link operation is serviced at minor loop completion.

If a system bus read or write is terminated with an error, the data transfer is stopped and the appropriate bus error flag set. In this case, the state of the channel's transfer control descriptor is updated by the eDMA engine with the current source address, destination address, and current iteration count at the point of the fault. When a system bus error occurs, the channel terminates after the next transfer. Due to pipeline effect, the next transfer is already in progress when the bus error is received by the eDMA. If a bus error occurs on the last read prior to beginning the write sequence, the write executes using the data captured during the bus error. If a bus error occurs on the last write prior to switching to the next read sequence, the read sequence executes before the channel terminates due to the destination bus error.

If an uncorrectable ECC error occurs during a peripheral bus access, the access is terminated with a bus error. The occurrence of an uncorrectable ECC error during an eDMA engine read causes the eDMA engine to stop the active channel immediately. The ECC error and channel number are recorded in the eDMA's Error Status register.

A transfer may be cancelled by software with the CR[CX] bit. When a cancel transfer request is recognized, the DMA engine stops processing the channel. The current read-write sequence is allowed to finish. If the cancel occurs on the last read-write sequence of a major or minor loop, the cancel request is discarded and the channel retires normally.

The error cancel transfer is the same as a cancel transfer except the Error Status register (DMAx\_ES) is updated with the cancelled channel number and ECX is set. The TCD of a cancelled channel contains the source and destination addresses of the last transfer saved in the TCD. If the channel needs to be restarted, you must re-initialize the TCD because the aforementioned fields no longer represent the original parameters. When a transfer is cancelled by the error cancel transfer mechanism, the channel number is loaded into DMA\_ES[ERRCHN] and ECX and VLD are set. In addition, an error interrupt may be generated if enabled.

### NOTE

The cancel transfer request allows the user to stop a large data transfer in the event the full data transfer is no longer needed. The cancel transfer bit does not abort the channel. It simply stops the transferring of data and then retires the channel through its normal shutdown sequence. The application software must handle the context of the cancel. If an interrupt is desired (or not), then the interrupt should be enabled (or disabled) before the cancel request. The application software must clean up the transfer control descriptor since the full transfer did not occur.

The occurrence of any error causes the eDMA engine to stop normal processing of the active channel immediately (it goes to its error processing states and the transaction to the system bus still has pipeline effect), and the appropriate channel bit in the eDMA error register is asserted. At the same time, the details of the error condition are loaded into the Error Status register (DMAx\_ES). The major loop complete indicators, setting the transfer control descriptor DONE flag and the possible assertion of an interrupt request, are not affected when an error is detected. After the error status has been updated, the eDMA engine continues operating by servicing the next appropriate channel. A channel that experiences an error condition is not automatically disabled. If a channel is terminated by an error and then issues another service request before the error is fixed, that channel executes and terminates with the same error condition.

### **16.5.3 Channel preemption**

Channel preemption is enabled on a per-channel basis by setting the DCHPRIn[ECP] bit. Channel preemption allows the executing channel's data transfers to temporarily suspend in favor of starting a higher priority channel. After the preempting channel has completed all its minor loop data transfers, the preempted channel is restored and resumes execution. After the restored channel completes one read/write sequence, it is again eligible for preemption. If any higher priority channel is requesting service, the restored channel is suspended and the higher priority channel is serviced. Nested preemption, that is, attempting to preempt a preempting channel, is not supported. After a preempting channel begins execution, it cannot be preempted. Preemption is available only when fixed arbitration is selected for both group and channel arbitration modes.

A channel's ability to preempt another channel can be disabled by setting DCHPRIn[DPA]. When a channel's preempt ability is disabled, that channel cannot suspend a lower priority channel's data transfer, regardless of the lower priority channel's ECP setting. This allows for a pool of low priority, large data-moving channels to be defined. These low priority channels can be configured to not preempt each other, thus preventing a low priority channel from consuming the preempt slot normally available to a true, high priority channel.

### **16.5.4 Performance**

This section addresses the performance of the eDMA module, focusing on two separate metrics:

- In the traditional data movement context, performance is best expressed as the peak data transfer rates achieved using the eDMA. In most implementations, this transfer rate is limited by the speed of the source and destination address spaces.
- In a second context where device-paced movement of single data values to/from peripherals is dominant, a measure of the requests that can be serviced in a fixed time is a more relevant metric. In this environment, the speed of the source and destination address spaces remains important. However, the microarchitecture of the eDMA also factors significantly into the resulting metric.

### 16.5.4.1 Peak transfer rates

The peak transfer rates for several different source and destination transfers are shown in the following tables. These tables assume:

- Internal SRAM can be accessed with zero wait-states when viewed from the system bus data phase
- All internal peripheral bus reads require two wait-states, and internal peripheral bus writes three wait-states, when viewed from the system bus data phase
- All internal peripheral bus accesses are 32-bits in size

#### NOTE

All architectures will not meet the assumptions listed above.  
See the SRAM configuration section for more information.

This table compares peak transfer rates based on different possible system speeds. Specific chips/devices may not support all system speeds listed.

**Table 16-1068. eDMA peak transfer rates (Mbytes/sec)**

| System Speed, Width | Internal SRAM-to-Internal SRAM | 32 bit internal peripheral bus-to-Internal SRAM | Internal SRAM-to-32 bit internal peripheral bus |
|---------------------|--------------------------------|-------------------------------------------------|-------------------------------------------------|
| 66.7 MHz, 64 bit    | 266.7                          | 66.6                                            | 53.3                                            |
| 83.3 MHz, 64 bit    | 333.3                          | 83.3                                            | 66.7                                            |
| 100.0 MHz, 64 bit   | 400.0                          | 100.0                                           | 80.0                                            |
| 133.3 MHz, 64 bit   | 533.3                          | 133.3                                           | 106.7                                           |
| 150.0 MHz, 64 bit   | 600.0                          | 150.0                                           | 120.0                                           |

Internal-SRAM-to-internal-SRAM transfers occur at the core's datapath width. For all transfers involving the internal peripheral bus, 32-bit transfer sizes are used. In all cases, the transfer rate includes the time to read the source plus the time to write the destination.

### 16.5.4.2 Peak request rates

The second performance metric is a measure of the number of DMA requests that can be serviced in a given amount of time. For this metric, assume that the peripheral request causes the channel to move a single internal peripheral bus-mapped operand to/from internal SRAM. The same timing assumptions used in the previous example apply to this calculation. In particular, this metric also reflects the time required to activate the channel.

The eDMA design supports the following hardware service request sequence. Note that the exact timing from Cycle 7 is a function of the response times for the channel's read and write accesses. In the case of an internal peripheral bus read and internal SRAM write, the combined data phase time is 4 cycles. For an SRAM read and internal peripheral bus write, it is 5 cycles.

**Table 16-1069. Hardware service request process**

| Cycle                                                     |                                                  | Description                                                                                                                                                                                                                                            |
|-----------------------------------------------------------|--------------------------------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| With internal peripheral bus read and internal SRAM write | With SRAM read and internal peripheral bus write |                                                                                                                                                                                                                                                        |
| 1                                                         |                                                  | eDMA peripheral request is asserted.                                                                                                                                                                                                                   |
| 2                                                         |                                                  | The eDMA peripheral request is registered locally in the eDMA module and qualified. TCD <sub>n</sub> _CSR[START] bit initiated requests start at this point with the registering of the user write to TCD <sub>n</sub> word 7.                         |
| 3                                                         |                                                  | Channel arbitration begins.                                                                                                                                                                                                                            |
| 4                                                         |                                                  | Channel arbitration completes. The transfer control descriptor local memory read is initiated.                                                                                                                                                         |
| 5–6                                                       |                                                  | The first two parts of the activated channel's TCD is read from the local memory. The memory width to the eDMA engine is 64 bits, so the entire descriptor can be accessed in four cycles                                                              |
| 7                                                         |                                                  | The first system bus read cycle is initiated, as the third part of the channel's TCD is read from the local memory. Depending on the state of the crossbar switch, arbitration at the system bus may insert an additional cycle of delay here.         |
| 8–11                                                      | 8–12                                             | The last part of the TCD is read in. This cycle represents the first data phase for the read, and the address phase for the destination write.                                                                                                         |
| 12                                                        | 13                                               | This cycle represents the data phase of the last destination write.                                                                                                                                                                                    |
| 13                                                        | 14                                               | The eDMA engine completes the execution of the inner minor loop and prepares to write back the required TCD <sub>n</sub> fields into the local memory. The TCD <sub>n</sub> word 7 is read and checked for channel linking or scatter/gather requests. |

*Table continues on the next page...*

**Table 16-1069. Hardware service request process (continued)**

| Cycle                                                     |                                                  | Description                                                                                                                                                                   |
|-----------------------------------------------------------|--------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| With internal peripheral bus read and internal SRAM write | With SRAM read and internal peripheral bus write |                                                                                                                                                                               |
| 14                                                        | 15                                               | The appropriate fields in the first part of the TCD <sub>n</sub> are written back into the local memory.                                                                      |
| 15                                                        | 16                                               | The fields in the second part of the TCD <sub>n</sub> are written back into the local memory. This cycle coincides with the next channel arbitration cycle start.             |
| 16                                                        | 17                                               | The next channel to be activated performs the read of the first part of its TCD from the local memory. This is equivalent to Cycle 4 for the first channel's service request. |

Assuming zero wait states on the system bus, DMA requests can be processed every 9 cycles. Assuming an average of the access times associated with internal peripheral bus-to-SRAM (4 cycles) and SRAM-to-internal peripheral bus (5 cycles), DMA requests can be processed every 11.5 cycles ( $4 + (4+5)/2 + 3$ ). This is the time from Cycle 4 to Cycle  $x + 5$ . The resulting peak request rate, as a function of the system frequency, is shown in the following table.

**Table 16-1070. eDMA peak request rate (MReq/sec)**

| System frequency (MHz) | Request rate<br>with zero wait states | Request rate<br>with wait states |
|------------------------|---------------------------------------|----------------------------------|
| 48.0                   | 5.3                                   | 4.2                              |
| 66.6                   | 7.4                                   | 5.8                              |
| 83.3                   | 9.2                                   | 7.2                              |
| 100.0                  | 11.1                                  | 8.7                              |
| 133.3                  | 14.8                                  | 11.6                             |
| 150.0                  | 16.6                                  | 13.0                             |

A general formula to compute the peak request rate with overlapping requests is:

$$\text{PEAKreq} = \text{freq} / [\text{entry} + (1 + \text{read\_ws}) + (1 + \text{write\_ws}) + \text{exit}]$$

where:

**Table 16-1071. Peak request formula operands**

| exit     | Channel shutdown (3 cycles)                             |

### 16.5.4.3 eDMA performance example

Consider a system with the following characteristics:

- Internal SRAM can be accessed with one wait-state when viewed from the system bus data phase
- All internal peripheral bus reads require two wait-states, and internal peripheral bus writes three wait-states viewed from the system bus data phase
- System operates at 150 MHz

For an SRAM to internal peripheral bus transfer,

$$\text{PEAKreq} = 150 \text{ MHz} / [ 4 + (1 + 1) + (1 + 3) + 3 ] \text{ cycles} = 11.5 \text{ Mreq/sec}$$

For an internal peripheral bus to SRAM transfer,

$$\text{PEAKreq} = 150 \text{ MHz} / [ 4 + (1 + 2) + (1 + 1) + 3 ] \text{ cycles} = 12.5 \text{ Mreq/sec}$$

Assuming an even distribution of the two transfer types, the average peak request rate would be:

$$\text{PEAKreq} = (11.5 \text{ Mreq/sec} + 12.5 \text{ Mreq/sec}) / 2 = 12.0 \text{ Mreq/sec}$$

The minimum number of cycles to perform a single read/write, zero wait states on the system bus, from a cold start where no channel is executing and eDMA is idle are:

- 11 cycles for a software, that is, a TCD<sub>n</sub>\_CSR[START] bit, request
- 12 cycles for a hardware, that is, an eDMA peripheral request signal, request

Two cycles account for the arbitration pipeline and one extra cycle on the hardware request resulting from the internal registering of the eDMA peripheral request signals. For the peak request rate calculations above, the arbitration and request registering is absorbed in or overlaps the previous executing channel.

**Note**

When channel linking or scatter/gather is enabled, a two cycle delay is imposed on the next channel selection and startup. This allows the link channel or the scatter/gather channel to be eligible and considered in the arbitration pool for next channel selection.

## 16.6 Initialization/application information

The following sections discuss initialization of the eDMA and programming considerations.

### 16.6.1 eDMA initialization

To initialize the eDMA:

1. Write to the CR if a configuration other than the default is desired.
2. Write the channel priority levels to the DCHPRI $_n$  registers if a configuration other than the default is desired.
3. Enable error interrupts in the EEI registers if so desired.
4. Write the 32-byte TCD for each channel that may request service.
5. Enable any hardware service requests via the ERQH and ERQL registers.
6. Request channel service via either:
  - Software: setting the TCD $_n$ \_CSR[START]
  - Hardware: slave device asserting its eDMA peripheral request signal

After any channel requests service, a channel is selected for execution based on the arbitration and priority levels written into the programmer's model. The eDMA engine reads the entire TCD, including the TCD control and status fields, as shown in the following table, for the selected channel into its internal address path module.

As the TCD is read, the first transfer is initiated on the internal bus, unless a configuration error is detected. Transfers from the source, as defined by TCD $_n$ \_SADDR, to the destination, as defined by TCD $_n$ \_DADDR, continue until the number of bytes specified by TCD $_n$ \_NBYTES are transferred.

When the transfer is complete, the eDMA engine's local TCD<sub>n</sub>\_SADDR, TCD<sub>n</sub>\_DADDR, and TCD<sub>n</sub>\_CITER are written back to the main TCD memory and any minor loop channel linking is performed, if enabled. If the major loop is exhausted, further post processing executes, such as interrupts, major loop channel linking, and scatter/gather operations, if enabled.

**Table 16-1072. TCD Control and Status fields**

| TCD <sub>n</sub> _CSR field name | Description                                                                                                             |
|----------------------------------|-------------------------------------------------------------------------------------------------------------------------|
| START                            | Control bit to start channel explicitly when using a software initiated DMA service (Automatically cleared by hardware) |
| ACTIVE                           | Status bit indicating the channel is currently in execution                                                             |
| DONE                             | Status bit indicating major loop completion (cleared by software when using a software initiated DMA service)           |
| D_REQ                            | Control bit to disable DMA request at end of major loop completion when using a hardware initiated DMA service          |
| BWC                              | Control bits for throttling bandwidth control of a channel                                                              |
| E_SG                             | Control bit to enable scatter-gather feature                                                                            |
| INT_HALF                         | Control bit to enable interrupt when major loop is half complete                                                        |
| INT_MAJ                          | Control bit to enable interrupt when major loop completes                                                               |

The following figure shows how each DMA request initiates one minor-loop transfer, or iteration, without CPU intervention. DMA arbitration can occur after each minor loop, and one level of minor loop DMA preemption is allowed. The number of minor loops in a major loop is specified by the beginning iteration count (BITER).

**Figure 16-1068. Example of multiple loop iterations**

The following figure lists the memory array terms and how the TCD settings interrelate.

Figure 16-1069. Memory array terms

## 16.6.2 Programming errors

The eDMA performs various tests on the transfer control descriptor to verify consistency in the descriptor data. Most programming errors are reported on a per channel basis with the exception of two errors: Group Priority Error (ES[GPE]) and channel priority error (ES[CPE]).

For all error types other than group or channel priority errors, the channel number causing the error is recorded in the Error Status register (DMAx\_ES). If the error source is not removed before the next activation of the problem channel, the error is detected and recorded again.

Channel priority errors are identified within a group once that group has been selected as the active group. For example:

1. The eDMA is configured for fixed group and fixed channel arbitration modes.
2. Group 1 is the highest priority and all channels are unique in that group.
3. Group 0 is the next highest priority and has two channels with the same priority level.
4. If Group 1 has any service requests, those requests will be executed.
5. After all of Group 1 requests have completed, Group 0 will be the next active group.

6. If Group 0 has a service request, then an undefined channel in Group 0 will be selected and a channel priority error will occur.
7. This repeats until the all of Group 0 requests have been removed or a higher priority Group 1 request comes in.

In this sequence, for item 2, the eDMA acknowledge lines will assert only if the selected channel is requesting service via the eDMA peripheral request signal. If interrupts are enabled for all channels, the user will get an error interrupt, but the channel number for the ERR register and the error interrupt request line may be wrong because they reflect the selected channel. A group priority error is global and any request in any group will cause a group priority error.

If priority levels are not unique, when any channel requests service, a channel priority error is reported. The highest channel/group priority with an active request is selected, but the lowest numbered channel/group with that priority is selected by arbitration and executed by the eDMA engine. The hardware service request handshake signals, error interrupts, and error reporting is associated with the selected channel.

### **16.6.3 Arbitration mode considerations**

This section discusses arbitration considerations for the eDMA.

#### **16.6.3.1 Fixed group arbitration, Fixed channel arbitration**

In this mode, the channel service request from the highest priority channel in the highest priority group is selected to execute. If the eDMA is programmed so that the channels within one group use "fixed" priorities, and that group is assigned the highest "fixed" priority of all groups, that group can take all the bandwidth of the eDMA controller. That is, no other groups will be serviced if there is always at least one DMA request pending on a channel in the highest priority group when the controller arbitrates the next DMA request. The advantage of this scenario is that latency can be small for channels that need to be serviced quickly. Preemption is available in this scenario only.

#### **16.6.3.2 Round-robin group arbitration, fixed channel arbitration**

At the occurrence of one or more DMA requests from one or more groups, the channel with the highest priority from a specific group will be serviced first. Groups are serviced starting with the highest group number with an service request and rotating through to the lowest group number containing a service request.

Once the channel request is serviced, the group round robin algorithm will select the highest pending request from the next group in the round robin sequence. Servicing continues round robin, always servicing the highest priority channel in the next group in the sequence, or just skipping a group if it has no pending requests.

If a channel requests service at a rate that equals or exceeds the round robin service rate, then that channel will always be serviced before lower priority channels in the same group, and thus the lower priority channels will never be serviced. The advantage of this scenario is that no one group will consume all the eDMA bandwidth. The highest priority channel selection latency is potentially greater than fixed/fixed arbitration. Excessive request rates on high priority channels could prevent the servicing of lower priority channels in the same group.

### 16.6.3.3 Round-robin group arbitration, round-robin channel arbitration

Groups will be serviced as described in [Round-robin group arbitration, fixed channel arbitration](#), but this time channels will be serviced in channel number order. Only one channel is serviced from each requesting group for each round robin pass through the groups.

Within each group, channels are serviced starting with the highest channel number and rotating through to the lowest channel number without regard to channel priority levels.

Because channels are serviced in round robin manner, any channel that generates DMA requests faster than a combination of the group round robin service rate and the channel service rate for its group will not prevent the servicing of other channels in its group. Any DMA requests that are not serviced are simply lost, but at least one channel will be serviced.

This scenario ensures that all channels will be guaranteed service at some point, regardless of the request rates. However, the potential latency could be quite high. All channels are treated equally. Priority levels are not used in round robin/round robin mode.

### 16.6.3.4 Fixed group arbitration, Round-robin channel arbitration

The highest priority group with a request will be serviced. Lower priority groups will be serviced if no pending requests exist in the higher priority groups.

Within each group, channels are serviced starting with the highest channel number and rotating through to the lowest channel number without regard to the channel priority levels assigned within the group.

This scenario could cause the same bandwidth consumption problem as indicated in [Fixed group arbitration](#), [Fixed channel arbitration](#), but all the channels in the highest priority group will be serviced. Service latency will be short on the highest priority group, but could potentially be very much longer as the group priority decreases.

## 16.6.4 Performing DMA transfers

This section presents examples on how to perform DMA transfers with the eDMA.

### 16.6.4.1 Single request

To perform a simple transfer of  $n$  bytes of data with one activation, set the major loop to one ( $\text{TCDn\_CITER} = \text{TCDn\_BITER} = 1$ ). The data transfer begins after the channel service request is acknowledged and the channel is selected to execute. After the transfer is complete, the  $\text{TCDn\_CSR}[\text{DONE}]$  bit is set and an interrupt generates if properly enabled.

For example, the following TCD entry is configured to transfer 16 bytes of data. The eDMA is programmed for one iteration of the major loop transferring 16 bytes per iteration. The source memory has a byte wide memory port located at 0x1000. The destination memory has a 32-bit port located at 0x2000. The address offsets are programmed in increments to match the transfer size: one byte for the source and four bytes for the destination. The final source and destination addresses are adjusted to return to their beginning values.

```
TCDn_CITER = TCDn_BITER = 1
TCDn_NBYTES = 16
TCDn_SADDR = 0x1000
TCDn_SOFF = 1
TCDn_ATTR[SSIZE] = 0
TCDn_SLAST = -16
TCDn_DADDR = 0x2000
TCDn_DOFF = 4
TCDn_ATTR[DSIZE] = 2
TCDn_DLAST_SGA = -16
TCDn_CSR[INT_MAJ] = 1
TCDn_CSR[START] = 1 (Should be written last after all other fields have been initialized)
All other TCDn fields = 0
```

This generates the following event sequence:

1. User write to the  $\text{TCDn\_CSR}[\text{START}]$  bit requests channel service.

2. The channel is selected by arbitration for servicing.
3. eDMA engine writes:  $\text{TCDn\_CSR}[\text{DONE}] = 0$ ,  $\text{TCDn\_CSR}[\text{START}] = 0$ ,  $\text{TCDn\_CSR}[\text{ACTIVE}] = 1$ .
4. eDMA engine reads: channel TCD data from local memory to internal register file.
5. The source-to-destination transfers are executed as follows:
  - a. Read byte from location 0x1000, read byte from location 0x1001, read byte from 0x1002, read byte from 0x1003.
  - b. Write 32-bits to location 0x2000 → first iteration of the minor loop.
  - c. Read byte from location 0x1004, read byte from location 0x1005, read byte from 0x1006, read byte from 0x1007.
  - d. Write 32-bits to location 0x2004 → second iteration of the minor loop.
  - e. Read byte from location 0x1008, read byte from location 0x1009, read byte from 0x100A, read byte from 0x100B.
  - f. Write 32-bits to location 0x2008 → third iteration of the minor loop.
  - g. Read byte from location 0x100C, read byte from location 0x100D, read byte from 0x100E, read byte from 0x100F.
  - h. Write 32-bits to location 0x200C → last iteration of the minor loop → major loop complete.
6. The eDMA engine writes:  $\text{TCDn\_SADDR} = 0x1000$ ,  $\text{TCDn\_DADDR} = 0x2000$ ,  $\text{TCDn\_CITER} = 1$  ( $\text{TCDn\_BITER}$ ).
7. The eDMA engine writes:  $\text{TCDn\_CSR}[\text{ACTIVE}] = 0$ ,  $\text{TCDn\_CSR}[\text{DONE}] = 1$ ,  $\text{INT}[n] = 1$ .
8. The channel retires and the eDMA goes idle or services the next channel.

### 16.6.4.2 Multiple requests

The following example transfers 32 bytes via two hardware requests, but is otherwise the same as the previous example. The only fields that change are the major loop iteration count and the final address offsets. The eDMA is programmed for two iterations of the major loop transferring 16 bytes per iteration. After the channel's hardware requests are enabled in the ERQ register, the slave device initiates channel service requests.

```
TCDn_CITER = TCDn_BITER = 2  
TCDn_SLAST = -32  
TCDn_DLAST_SGA = -32
```

This would generate the following sequence of events:

1. First hardware, that is, eDMA peripheral, request for channel service.
2. The channel is selected by arbitration for servicing.
3. eDMA engine writes:  $\text{TCDn\_CSR}[\text{DONE}] = 0$ ,  $\text{TCDn\_CSR}[\text{START}] = 0$ ,  $\text{TCDn\_CSR}[\text{ACTIVE}] = 1$ .
4. eDMA engine reads: channel  $\text{TCDn}$  data from local memory to internal register file.
5. The source to destination transfers are executed as follows:
  - a. Read byte from location 0x1000, read byte from location 0x1001, read byte from 0x1002, read byte from 0x1003.
  - b. Write 32-bits to location 0x2000 → first iteration of the minor loop.
  - c. Read byte from location 0x1004, read byte from location 0x1005, read byte from 0x1006, read byte from 0x1007.
  - d. Write 32-bits to location 0x2004 → second iteration of the minor loop.
  - e. Read byte from location 0x1008, read byte from location 0x1009, read byte from 0x100A, read byte from 0x100B.
  - f. Write 32-bits to location 0x2008 → third iteration of the minor loop.
  - g. Read byte from location 0x100C, read byte from location 0x100D, read byte from 0x100E, read byte from 0x100F.
  - h. Write 32-bits to location 0x200C → last iteration of the minor loop.
6. eDMA engine writes:  $\text{TCDn\_SADDR} = 0x1010$ ,  $\text{TCDn\_DADDR} = 0x2010$ ,  $\text{TCDn\_CITER} = 1$ .
7. eDMA engine writes:  $\text{TCDn\_CSR}[\text{ACTIVE}] = 0$ .
8. The channel retires → one iteration of the major loop. The eDMA goes idle or services the next channel.
9. Second hardware, that is, eDMA peripheral, requests channel service.
10. The channel is selected by arbitration for servicing.
11. eDMA engine writes:  $\text{TCDn\_CSR}[\text{DONE}] = 0$ ,  $\text{TCDn\_CSR}[\text{START}] = 0$ ,  $\text{TCDn\_CSR}[\text{ACTIVE}] = 1$ .

12. eDMA engine reads: channel TCD data from local memory to internal register file.
13. The source to destination transfers are executed as follows:
  - a. Read byte from location 0x1010, read byte from location 0x1011, read byte from 0x1012, read byte from 0x1013.
  - b. Write 32-bits to location 0x2010 → first iteration of the minor loop.
  - c. Read byte from location 0x1014, read byte from location 0x1015, read byte from 0x1016, read byte from 0x1017.
  - d. Write 32-bits to location 0x2014 → second iteration of the minor loop.
  - e. Read byte from location 0x1018, read byte from location 0x1019, read byte from 0x101A, read byte from 0x101B.
  - f. Write 32-bits to location 0x2018 → third iteration of the minor loop.
  - g. Read byte from location 0x101C, read byte from location 0x101D, read byte from 0x101E, read byte from 0x101F.
  - h. Write 32-bits to location 0x201C → last iteration of the minor loop → major loop complete.
14. eDMA engine writes:  $\text{TCDn\_SADDR} = 0x1000$ ,  $\text{TCDn\_DADDR} = 0x2000$ ,  $\text{TCDn\_CITER} = 2$  ( $\text{TCDn\_BITER}$ ).
15. eDMA engine writes:  $\text{TCDn\_CSR}[\text{ACTIVE}] = 0$ ,  $\text{TCDn\_CSR}[\text{DONE}] = 1$ ,  $\text{INT}[n] = 1$ .
16. The channel retires → major loop complete. The eDMA goes idle or services the next channel.

### 16.6.4.3 Using the modulo feature

The modulo feature of the eDMA provides the ability to implement a circular data queue in which the size of the queue is a power of 2. MOD is a 5-bit field for the source and destination in the TCD, and it specifies which lower address bits increment from their original value after the address+offset calculation. All upper address bits remain the same as in the original value. A setting of 0 for this field disables the modulo feature.

The following table shows how the transfer addresses are specified based on the setting of the MOD field. Here a circular buffer is created where the address wraps to the original value while the 28 upper address bits (0x1234567x) retain their original value. In this example the source address is set to 0x12345670, the offset is set to 4 bytes and the MOD field is set to 4, allowing for a 2<sup>4</sup> byte (16-byte) size queue.

**Table 16-1073. Modulo example**

| Transfer Number | Address    |
|-----------------|------------|
| 1               | 0x12345670 |
| 2               | 0x12345674 |
| 3               | 0x12345678 |
| 4               | 0x1234567C |
| 5               | 0x12345670 |
| 6               | 0x12345674 |

## 16.6.5 Monitoring transfer descriptor status

This section discusses how to monitor eDMA status.

### 16.6.5.1 Testing for minor loop completion

There are two methods to test for minor loop completion when using software initiated service requests. The first is to read the TCD<sub>n</sub>\_CITER field and test for a change. Another method may be extracted from the sequence shown below. The second method is to test the TCD<sub>n</sub>\_CSR[START] bit and the TCD<sub>n</sub>\_CSR[ACTIVE] bit. The minor-loop-complete condition is indicated by both bits reading zero after the TCD<sub>n</sub>\_CSR[START] was set. Polling the TCD<sub>n</sub>\_CSR[ACTIVE] bit may be inconclusive, because the active status may be missed if the channel execution is short in duration.

The TCD status bits execute the following sequence for a software activated channel:

| Stage | TCD <sub>n</sub> _CSR bits |        |      | State                                            |
|-------|----------------------------|--------|------|--------------------------------------------------|
|       | START                      | ACTIVE | DONE |                                                  |
| 1     | 1                          | 0      | 0    | Channel service request via software             |
| 2     | 0                          | 1      | 0    | Channel is executing                             |
| 3a    | 0                          | 0      | 0    | Channel has completed the minor loop and is idle |
| 3b    | 0                          | 0      | 1    | Channel has completed the major loop and is idle |

The best method to test for minor-loop completion when using hardware, that is, peripheral, initiated service requests is to read the `TCDn_CITER` field and test for a change. The hardware request and acknowledge handshake signals are not visible in the programmer's model.

The TCD status bits execute the following sequence for a hardware-activated channel:

| Stage | TCDn_CSR bits |        |      | State                                                              |
|-------|---------------|--------|------|--------------------------------------------------------------------|
|       | START         | ACTIVE | DONE |                                                                    |
| 1     | 0             | 0      | 0    | Channel service request via hardware (peripheral request asserted) |
| 2     | 0             | 1      | 0    | Channel is executing                                               |
| 3a    | 0             | 0      | 0    | Channel has completed the minor loop and is idle                   |
| 3b    | 0             | 0      | 1    | Channel has completed the major loop and is idle                   |

For both activation types, the major-loop-complete status is explicitly indicated via the `TCDn_CSR[DONE]` bit.

The `TCDn_CSR[START]` bit is cleared automatically when the channel begins execution regardless of how the channel activates.

### 16.6.5.2 Reading the transfer descriptors of active channels

The eDMA reads back the true `TCDn_SADDR`, `TCDn_DADDR`, and `TCDn_NBYTES` values if read while a channel executes. The true values of the `SADDR`, `DADDR`, and `NBYTES` are the values the eDMA engine currently uses in its internal register file and not the values in the TCD local memory for that channel. The addresses, `SADDR` and `DADDR`, and `NBYTES`, which decrement to zero as the transfer progresses, can give an indication of the progress of the transfer. All other values are read back from the TCD local memory.

### 16.6.5.3 Checking channel preemption status

Preemption is available only when fixed arbitration is selected for both group and channel arbitration modes. A preemptive situation is one in which a preempt-enabled channel runs and a higher priority request becomes active. When the eDMA engine is not operating in fixed group, fixed channel arbitration mode, the determination of the actively running relative priority outstanding requests become undefined. Channel and/or group priorities are treated as equal, that is, constantly rotating, when Round-Robin Arbitration mode is selected.

The TCD $n$ \_CSR[ACTIVE] bit for the preempted channel remains asserted throughout the preemption. The preempted channel is temporarily suspended while the preempting channel executes one major loop iteration. If two TCD $n$ \_CSR[ACTIVE] bits are set simultaneously in the global TCD map, a higher priority channel is actively preempting a lower priority channel.

## 16.6.6 Channel Linking

Channel linking (or chaining) is a mechanism where one channel sets the TCD $n$ \_CSR[START] bit of another channel (or itself), therefore initiating a service request for that channel. When properly enabled, the EDMA engine automatically performs this operation at the major or minor loop completion.

The minor loop channel linking occurs at the completion of the minor loop (or one iteration of the major loop). The TCD $n$ \_CITER[E\_LINK] field determines whether a minor loop link is requested. When enabled, the channel link is made after each iteration of the major loop except for the last. When the major loop is exhausted, only the major loop channel link fields are used to determine if a channel link should be made. For example, the initial fields of:

```
TCDn_CITER[E_LINK] = 1
TCDn_CITER[LINKCH] = 0xC
TCDn_CITER[CITER] value = 0x4
TCDn_CSR[MAJOR_E_LINK] = 1
TCDn_CSR[MAJOR_LINKCH] = 0x7
```

executes as:

1. Minor loop done → set TCD12\_CSR[START] bit
2. Minor loop done → set TCD12\_CSR[START] bit
3. Minor loop done → set TCD12\_CSR[START] bit
4. Minor loop done, major loop done → set TCD7\_CSR[START] bit

When minor loop linking is enabled (TCD $n$ \_CITER[E\_LINK] = 1), the TCD $n$ \_CITER[CITER] field uses a nine bit vector to form the current iteration count. When minor loop linking is disabled (TCD $n$ \_CITER[E\_LINK] = 0), the TCD $n$ \_CITER[CITER] field uses a 15-bit vector to form the current iteration count. The bits associated with the TCD $n$ \_CITER[LINKCH] field are concatenated onto the CITER value to increase the range of the CITER.

## Note

The TCD $n$ \_CITER[E\_LINK] bit and the TCD $n$ \_BITER[E\_LINK] bit must equal or a configuration error is reported. The CITER and BITER vector widths must be equal to calculate the major loop, half-way done interrupt point.

The following table summarizes how a DMA channel can link to another DMA channel, i.e, use another channel's TCD, at the end of a loop.

**Table 16-1074. Channel Linking Parameters**

| Desired Link Behavior     | TCD Control Field Name | Description                                                                    |
|---------------------------|------------------------|--------------------------------------------------------------------------------|
| Link at end of Minor Loop | CITER[E_LINK]          | Enable channel-to-channel linking on minor loop completion (current iteration) |
|                           | CITER[LINKCH]          | Link channel number when linking at end of minor loop (current iteration)      |
| Link at end of Major Loop | CSR[MAJOR_E_LINK]      | Enable channel-to-channel linking on major loop completion                     |
|                           | CSR[MAJOR_LINKCH]      | Link channel number when linking at end of major loop                          |

## 16.6.7 Dynamic programming

This section provides recommended methods to change the programming model during channel execution.

### 16.6.7.1 Dynamically changing the channel priority

The following two options are recommended for dynamically changing channel priority levels:

1. Switch to Round-Robin Channel Arbitration mode, change the channel priorities, then switch back to Fixed Arbitration mode,
2. Disable all the channels within a group, change the channel priorities within that group only, then enable the appropriate channels.

The following two options are available for dynamically changing group priority levels:

1. Switch to Round-Robin Group Arbitration mode, change the group priorities, then switch back to Fixed Arbitration mode,
2. Disable all channels, change the group priorities, then enable the appropriate channels.

### 16.6.7.2 Dynamic channel linking

Dynamic channel linking is the process of setting the TCD.major.e\_link bit during channel execution (see the diagram in [TCD structure](#)). This bit is read from the TCD local memory at the end of channel execution, thus allowing the user to enable the feature during channel execution.

Because the user is allowed to change the configuration during execution, a coherency model is needed. Consider the scenario where the user attempts to execute a dynamic channel link by enabling the TCD.major.e\_link bit at the same time the eDMA engine is retiring the channel. The TCD.major.e\_link would be set in the programmer's model, but it would be unclear whether the actual link was made before the channel retired.

The following coherency model is recommended when executing a dynamic channel link request.

1. Write 1 to the TCD.major.e\_link bit.
2. Read back the TCD.major.e\_link bit.
3. Test the TCD.major.e\_link request status:
  - If TCD.major.e\_link = 1, the dynamic link attempt was successful.
  - If TCD.major.e\_link = 0, the attempted dynamic link did not succeed (the channel was already retiring).

For this request, the TCD local memory controller forces the TCD.major.e\_link bit to zero on any writes to a channel's TCD.word7 after that channel's TCD.done bit is set, indicating the major loop is complete.

#### NOTE

The user must clear the TCD.done bit before writing the TCD.major.e\_link bit. The TCD.done bit is cleared automatically by the eDMA engine after a channel begins execution.

### 16.6.7.3 Dynamic scatter/gather

Scatter/gather is the process of automatically loading a new TCD into a channel. It allows a DMA channel to use multiple TCDs; this enables a DMA channel to scatter the DMA data to multiple destinations or gather it from multiple sources. When scatter/gather is enabled and the channel has finished its major loop, a new TCD is fetched from system memory and loaded into that channel's descriptor location in eDMA programmer's model, thus replacing the current descriptor.

Because the user is allowed to change the configuration during execution, a coherency model is needed. Consider the scenario where the user attempts to execute a dynamic scatter/gather operation by enabling the TCD.e\_sg bit at the same time the eDMA engine is retiring the channel. The TCD.e\_sg would be set in the programmer's model, but it would be unclear whether the actual scatter/gather request was honored before the channel retired.

Two methods for this coherency model are shown in the following subsections. Method 1 has the advantage of reading the major.linkch field and the e\_sg bit with a single read. For both dynamic channel linking and scatter/gather requests, the TCD local memory controller forces the TCD.major.e\_link and TCD.e\_sg bits to zero on any writes to a channel's TCD.word7 if that channel's TCD.done bit is set indicating the major loop is complete.

### NOTE

The user must clear the TCD.done bit before writing the TCD.major.e\_link or TCD.e\_sg bits. The TCD.done bit is cleared automatically by the eDMA engine after a channel begins execution.

#### 16.6.7.3.1 Method 1 (channel not using major loop channel linking)

For a channel not using major loop channel linking, the coherency model described here may be used for a dynamic scatter/gather request.

When the TCD.major.e\_link bit is zero, the TCD.major.linkch field is not used by the eDMA. In this case, the TCD.major.linkch bits may be used for other purposes. This method uses the TCD.major.linkch field as a TCD identification (ID).

1. When the descriptors are built, write a unique TCD ID in the TCD.major.linkch field for each TCD associated with a channel using dynamic scatter/gather.
2. Write 1b to the TCD.d\_req bit.

Should a dynamic scatter/gather attempt fail, setting the TCD.d\_req bit will prevent a future hardware activation of this channel. This stops the channel from executing with a destination address (daddr) that was calculated using a scatter/gather address (written in the next step) instead of a dlast final offset value.

3. Write the TCD.dlast\_sga field with the scatter/gather address.
4. Write 1b to the TCD.e\_sg bit.
5. Read back the 16 bit TCD control/status field.

6. Test the TCD.e\_sg request status and TCD.major.linkch value:

If e\_sg = 1b, the dynamic link attempt was successful.

If e\_sg = 0b and the major.linkch (ID) did not change, the attempted dynamic link did not succeed (the channel was already retiring).

If e\_sg = 0b and the major.linkch (ID) changed, the dynamic link attempt was successful (the new TCD's e\_sg value cleared the e\_sg bit).

### 16.6.7.3.2 Method 2 (channel using major loop channel linking)

For a channel using major loop channel linking, the coherency model described here may be used for a dynamic scatter/gather request. This method uses the TCD.dlast\_sga field as a TCD identification (ID).

1. Write 1b to the TCD.d\_req bit.

Should a dynamic scatter/gather attempt fail, setting the d\_req bit will prevent a future hardware activation of this channel. This stops the channel from executing with a destination address (daddr) that was calculated using a scatter/gather address (written in the next step) instead of a dlast final offset value.

2. Write the TCD.dlast\_sga field with the scatter/gather address.

3. Write 1b to the TCD.e\_sg bit.

4. Read back the TCD.e\_sg bit.

5. Test the TCD.e\_sg request status:

If e\_sg = 1b, the dynamic link attempt was successful.

If e\_sg = 0b, read the 32 bit TCD dlast\_sga field.

If e\_sg = 0b and the dlast\_sga did not change, the attempted dynamic link did not succeed (the channel was already retiring).

If e\_sg = 0b and the dlast\_sga changed, the dynamic link attempt was successful (the new TCD's e\_sg value cleared the e\_sg bit).

### 16.6.8 Suspend/resume a DMA channel with active hardware service requests

The DMA allows the user to move data from memory or peripheral registers to another location in memory or peripheral registers without CPU interaction. Once the DMA and peripherals have been configured and are active, it is rare to suspend a peripheral's service request dynamically. In this scenario, there are certain restrictions to disabling a DMA hardware service request. For coherency, a specific procedure must be followed. This section provides guidance on how to coherently suspend and resume a Direct Memory Access (DMA) channel when the DMA is triggered by a slave module such as the Serial Peripheral Interface (DSPI), ADC, or other module.

#### 16.6.8.1 Suspend an active DMA channel

To suspend an active DMA channel:

1. Stop the DMA service request at the peripheral first. Confirm it has been disabled by reading back the appropriate register in the peripheral.
2. Check to ensure there is no service request to the DMA channel being suspended. Then disable the hardware service request by clearing the ERQ bit on the appropriate DMA channel.

#### 16.6.8.2 Resume a DMA channel

To resume a DMA channel:

1. Enable the DMA service request on the appropriate channel by setting its ERQ bit.
2. Enable the DMA service request at the peripheral.

For example, assume a DSPI module is set as a master for transmitting data via a DMA service request when the DSPI\_TXFIFO has an empty slot. The DMA will transfer the next command and data to the TXFIFO upon the request. If the user needs to suspend the DMA/DSPI transfer loop, perform the following steps:

1. Disable the DMA service request at the source by writing 0 to DSPI\_RSER[TFFF\_RE] . Confirm that DSPI\_RSER[TFFF\_RE] is 0.
2. Ensure there is no DMA service request from the DSPI by verifying that DMA\_HRS[HRS<sub>n</sub>] is 0 for the appropriate channel. If no service request is present, disable the DMA channel by clearing the channel's ERQ bit. If a service request is present, wait until the request has been processed and the HRS bit reads zero.

# Chapter 17

## Error Injection Module (EIM)

### 17.1 Chip-specific EIM information

This chip has one instance of the EIM.

#### 17.1.1 EIM channels

The EIM on this chip supports 6 channels. The number of each channel corresponds to:

- A field in the EIM's EICHEN register
- An EICHD $n$ \_Word0 register
- An EICHD $n$ \_Word1 register
- An EICHD $n$ \_Word2 register

#### 17.1.2 EIM channel assignments

Each EIM channel corresponds to a specific RAM array target. The EIM channel can inject errors on accesses to that specific RAM array. The following table shows the channel assignments.

**Table 17-1. RAM array targets of EIM channels**

| EIM channel | RAM array target |
|-------------|------------------|
| 0           | PRAMC_0          |
| 1           | PRAMC_1          |
| 2           | FEC MIB          |
| 3           | FEC RIF          |
| 4           | eDMA_A TCD       |
| 5           | eDMA_B TCD       |

### 17.1.3 EIM\_EICHDN\_Word register bit mapping

The following table shows the implemented bits of the [Error Injection Channel Descriptor, Word0 \(EIM\\_EICHDN\\_WORD0\)](#), [Error Injection Channel Descriptor, Word1 \(EIM\\_EICHDN\\_WORD1\)](#), and [Error Injection Channel Descriptor, Word2 \(EIM\\_EICHDN\\_WORD2\)](#) registers for each channel.

| Off set | 0                                     | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9        | 10 | 11 | 12 | 13 | 14 | 15 | 16 | 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28                                 | 29 | 30 | 31 |
|---------|---------------------------------------|---|---|---|---|---|---|---|---|----------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|------------------------------------|----|----|----|
| 100     | PRAMC_0 CHKBIT_MASK                   |   |   |   |   |   |   |   |   | Reserved |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 104     | PRAMC_0 B0_3DATA_MASK (bits 63-32)    |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 108     | PRAMC_0 B4_7DATA_MASK (bits 31-0)     |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 200     | PRAMC_1 CHKBIT_MASK                   |   |   |   |   |   |   |   |   | Reserved |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 204     | PRAMC_1 B0_3DATA_MASK (bits 63-32)    |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 208     | PRAMC_1 B4_7DATA_MASK (bits 31-0)     |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 300     | FEC MIB CHKBIT_MASK                   |   |   |   |   |   |   |   |   | Reserved |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 304     | FEC MIB B0_3DATA_MASK (bits 31-0)     |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 308     | Reserved                              |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 400     | FEC RIF CHKBIT_MASK                   |   |   |   |   |   |   |   |   | Reserved |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 404     | Reserved                              |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    | FEC RIF B0_3DATA_MASK (bits 35-32) |    |    |    |
| 408     | FEC RIF B4_7DATA_MASK (bits 31-0)     |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 500     | eDMA_A TCD CHKBIT_MASK                |   |   |   |   |   |   |   |   | Reserved |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 504     | eDMA_A TCD B0_3DATA_MASK (bits 63-32) |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 508     | eDMA_A TCD B4_7DATA_MASK (bits 31-0)  |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 600     | eDMA_B TCD CHKBIT_MASK                |   |   |   |   |   |   |   |   | Reserved |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 604     | eDMA_B TCD B0_3DATA_MASK (bits 63-32) |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |
| 608     | eDMA_B TCD B4_7DATA_MASK (bits 31-0)  |   |   |   |   |   |   |   |   |          |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |                                    |    |    |    |

## 17.2 Introduction

The Error Injection module is mainly used for diagnostic purposes. It provides a method for diagnostic coverage of the peripheral memories. See the chip-specific EIM information to determine which peripheral memories are supported by this method.

## 17.2.1 Overview

The Error Injection Module (EIM) provides support for inducing single-bit and multi-bit inversions on read data when accessing peripheral RAMs. Injecting faults on memory accesses can be used to exercise the SEC-DED ECC function of the related system.

### NOTE

The following diagram shows an example EIM implementation with a 64-bit read data bus and an 8-bit checkbit bus.

Figure 17-1. EIM functional block diagram (64-bit read data bus and 8-bit checkbit bus)

## 17.2.2 Features

The EIM includes these features:

- Supports 6 error injection channels
- Protection against accidental enable and reconfiguration error injection function via two-stage enable mechanism

## 17.3 Memory map and register definition

The EIM provides an IPS programming model mapped to an on-platform peripheral slot.

### Programming model access

All system bus masters can access the programming model:

- Only in supervisor mode
- Using only 32-bit (word) accesses

Any of the following attempted references to the programming model generates an IPS error termination:

- In user mode
- Using non-32-bit access sizes
- To undefined (reserved) addresses

Attempted updates to the programming model while the EIM is in the midst of an operation will result in non-deterministic behavior.

### Error injection channel descriptor: function and structure

Each error injection channel descriptor:

- Specifies a mask that defines which bits of the read data and checkbit bus from target RAM are inverted on a read access.
- Consists of a 128-bit (16-byte) structure, composed of four 32-bit words, in the EIM programming model.

- Each descriptor consists of Error Injection Channel Descriptor Word0-1 (EICHD $n$ \_WORD0-1) and, depending on the implementation, Word2 (EICHD $n$ \_WORD2).
- When Word2 is unused, the corresponding word in the 16-byte structure is unused.
- The fourth word in the 16-byte structure is always unused.

The multiple channel descriptors are organized sequentially.

### EIM memory map

| Address offset (hex) | Register name                                                | Width (in bits) | Access | Reset value | Section/ page              |

| 0–30<br>Reserved | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                         |
| 31<br>GEIEN      | Global Error Injection Enable<br><br>This bit globally enables or disables the error injection function of the EIM. This field is initialized by hardware reset.<br><br>0 Disabled<br>1 Enabled |

## 17.3.2 Error Injection Channel Enable register (EIM\_EICHEN)

Each field of the Error Injection Channel Enable register (EICHEN) is used to enable or disable the corresponding error injection channel.

### NOTE

To enable an error injection channel, the Global Error Injection Enable (EIMCR[GEIEN]) field must also be asserted.

Address: 0h base + 4h offset = 4h

**17.3.3 Error Injection Channel Descriptor, Word0  
(EIM\_EICHD<sub>n</sub>\_WORD0)**

The first word of the Error Injection Channel Descriptor defines a left-justified mask field (CHKBIT\_MASK) whose width is up to 8 bits. Each bit of CHKBIT\_MASK specifies whether the corresponding bit of the checkbit bus from the target RAM should be inverted or remain unmodified on read accesses. Successful writes to this field clear the corresponding error injection channel valid bit, EICHEN[EICH<sub>n</sub>EN].

Address: 0h base + 100h offset + (256d × i), where i=0d to 5d

## 17.4 Functional description

The EIM provides protection against accidental enabling and reconfiguration of the error injection function by enforcing a two-stage enablement mechanism. To properly enable the error injection mechanism for a channel:

- Write 1 to the EICHEN[EICH<sub>n</sub>EN] field, where *n* denotes the channel number.
- Write 1 to EIMCR[GEIEN].

### NOTE

When the use case for a channel requires writing any EICHD<sub>n</sub>\_WORD register, write the EICHD<sub>n</sub>\_WORD register before executing the two-stage enablement mechanism. A successful write to any EICHD<sub>n</sub>\_WORD register clears the corresponding EICHEN[EICH<sub>n</sub>EN] field.

The EIM supports 6 error injection channels. Each channel:

- is assigned to a single memory array interface.
- intercepts the assigned memory read data bus and checkbit bus and injects errors by inverting the value transmitted for selected bits on each bus line.

On a memory read access, the applicable EICHD<sub>n</sub>\_WORD registers define which bits of the read data and/or checkbit bus to invert.

Figure 17-1 depicts the interception and override of a 64-bit read data bus and an 8-bit checkbit data bus for an example memory array.

### 17.4.1 Error injection scenarios

The EIM supports these cases of error injection:

- To generate a single-bit error, invert only 1 bit of the CHKBIT\_MASK or DATA\_MASK in the EICHD $n$ \_WORD registers.
- To generate a multi-bit error, invert only 2 bits of the CHKBIT\_MASK or DATA\_MASK in the EICHD $n$ \_WORD registers.

#### NOTE

An attempt to invert more than 2 bits in one operation might result in undefined behavior.

# Chapter 18

## Error Reporting Module (ERM)

### 18.1 Chip-specific ERM information

This chip has one instance of the ERM.

#### 18.1.1 ERM memory channels

The ERM on this chip supports 20 memory channels. The number of each memory channel corresponds to:

- A field in the ERM's CR0, CR1, or CR2 register
- A field in the ERM's SR0, SR1, or SR2 register
- An ERM\_EAR<sub>n</sub> register
- An ERM\_SYN<sub>n</sub> register

#### 18.1.2 Sources of memory error events

Each ERM channel corresponds to a source of potential memory error events. The following table shows the channel assignments.

**Table 18-1. Memory error event sources for ERM channels**

| ERM channel | Memory event source     |
|-------------|-------------------------|
| 0           | PRAMC_0                 |
| 1           | PRAMC_1                 |
| 2           | eDMA_A TCD <sup>1</sup> |
| 3           | eDMA_B TCD <sup>1</sup> |
| 4           | FEC MIB <sup>1</sup>    |

*Table continues on the next page...*

**Table 18-1. Memory error event sources for ERM channels (continued)**

| ERM channel | Memory event source  |
|-------------|----------------------|
| 5           | FEC RIF <sup>1</sup> |
| 6           | PFLASH port 0        |
| 7           | PFLASH port 1        |
| 8           | AIPS_0               |
| 9           | AIPS_1               |
| 10          | FEC e2eECC           |
| 11          | CSE                  |
| 13          | Core0 instruction    |
| 14          | Core0 data           |
| 15          | Core1 instruction    |
| 16          | Core1 data           |
| 17          | eDMA_A e2eECC        |
| 18          | eDMA_B e2eECC        |

1. For these memory elements, the error address captured is the relative array address and not the system address.

### 18.1.3 Managing single-bit faults of TCD RAM for eDMA\_A

When a single-bit ECC event occurs during a read of the TCD RAM for eDMA\_A, the fault is correctly identified and forwarded to the ERM. However, the fault is not corrected before being used by eDMA\_A.

To prevent eDMA\_A's use of single-bit faults from the TCD RAM for eDMA\_A: Ensure that ERM\_CR0[ESCIE2] is set to 1 to enable the ERM to trigger an interrupt, and use the interrupt to manage properly any single-bit fault that occurs.

## 18.2 Introduction

### 18.2.1 Overview

The Error Reporting Module (ERM) provides information and optional interrupt notification on memory error events associated with ECC (Error Correction Code). The ERM collects ECC events on memory accesses for platform local memory arrays, such as flash memory, system RAM, or peripheral RAMs. See the chip-specific ERM information for details about supported memory sources and specific memory channel assignments.

## 18.2.2 Features

The ERM includes these features:

- Capture address and syndrome information on single-bit correction and non-correctable ECC events
- Optional interrupt notification on captured ECC events
- Support for ECC event capturing for memory sources, with individual reporting fields and interrupt configuration per memory channel.

## 18.3 Memory map and register definition

The ERM provides an IPS programming model mapped to an on-platform peripheral slot. The programming model can only be referenced using a 32-bit (word) access. Attempted references using different access sizes or in user mode generate an IPS error termination. The ERM allows access to the programming model by all system bus masters.

The programming model can only be accessed in supervisor mode.

Attempted accesses to undefined (reserved) memory regions can result in undefined behavior.

Attempted updates to the programming model while the ERM module is in the middle of an operation will result in non-deterministic behavior.

**ERM memory map**

### 18.3.1 ERM Configuration Register (ERM\_CR0)

The ERM Configuration Register is a 32-bit control register for configuring the interrupt notification capability for memory channels 0 to 7.

Address: 0h base + 0h offset = 0h

## 18.3.2 ERM Configuration Register (ERM\_CR1)

The ERM Configuration Register is a 32-bit control register for configuring the interrupt notification capability for memory channels 8 to 15.

Address: 0h base + 4h offset = 4h

**18.3.3 ERM Configuration Register (ERM\_CR2)**

The ERM Configuration Register is a 32-bit control register for configuring the interrupt notification capability for memory channels 16 to 19.

Address: 0h base + 8h offset = 8h

### 18.3.4 ERM Status Register (ERM\_SR0)

The ERM Status Register is a 32-bit control register for signaling which types of ECC events have been detected for each memory channel. The register signals the last memory event to be detected for memory channels 0 to 7.

Address: 0h base + 10h offset = 10h

| Bit   | 0    | 1    | 2  | 3  | 4    | 5    | 6  | 7  | 8    | 9    | 10 | 11 | 12   | 13   | 14 | 15 |

### 18.3.5 ERM Status Register (ERM\_SR1)

The ERM Status Register is a 32-bit control register for signaling which types of ECC events have been detected for each memory channel. The register signals the last memory event to be detected for memory channels 8 to 15.

Address: 0h base + 14h offset = 14h

### 18.3.6 ERM Status Register (ERM\_SR2)

The ERM Status Register is a 32-bit control register for signaling which types of ECC events have been detected for each memory channel. The register signals the last memory event to be detected for memory channels 16 to 19.

Address: 0h base + 18h offset = 18h

| 0–31<br>EAR | Memory $n$ Error Address - This field contains the faulting system address of the last recorded ECC event on Memory $n$ .<br><b>NOTE:</b> Refer to the chip-specific ERM information for details on Memory $n$ mapping. |

### 18.3.8 ERM Memory $n$ Syndrome Register (ERM\_SYN $n$ )

The ERM\_SYN $n$  is a 32-bit register for capturing the calculated syndrome of the last ECC event on Memory  $n$ , where  $n$  denotes the memory channel. Any attempted write to ERM\_SYN $n$  is ignored. The syndrome value identifies the pertinent bit position on a correctable, single-bit data inversion or a non-correctable, single-bit address inversion. The syndrome value does not provide any additional diagnostic information on non-correctable, multi-bit inversions.

Address: 0h base + 104h offset + (16d × i), where i=0d to 19d

|       |          |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |

| 8–31<br>Reserved | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                  |

## 18.4 Functional description

### 18.4.1 Single-bit correction events

When a single-bit correction event on Memory  $n$  is detected, the ERM:

- Records the event by changing to 1 the value of the applicable Status Register bit: ERM\_SR $x$ [SBC $n$ ]
- Records the corresponding access address that initiated the event in the Memory  $n$  Error Address Register: ERM\_EAR $n$
- Stores the corresponding ECC syndrome in the Memory  $n$  Error Syndrome Register: ERM\_SYN $n$ . This register identifies the bit position of the corrected data on single-bit data inversion.

The ERM holds event information only for the last reported event.

To clear the record of an event, write 1 to ERM\_SRx[SBCn] to change its value to 0.

#### 18.4.1.1 Optional interrupt notification for single-bit correction events

The ERM provides an option to generate an interrupt notification upon the report of a single-bit correction event. This sequence describes how to use the option:

1. To enable interrupt notifications for single-bit correction events on Memory  $n$ , set ERM\_CRx[ESCIEn] to 1.
2. Subsequently, when a single-bit correction event on Memory  $n$  is detected, the ERM:
  - Records the event and address and stores the ECC syndrome as usual
  - Additionally sends an interrupt notification corresponding to the event
3. To clear both the record of an event and the corresponding interrupt notification, write 1 to ERM\_SRx[SBCn] to change its value to 0.

#### 18.4.2 Non-correctable error events

When a non-correctable ECC error event on Memory  $n$  is detected, the ERM:

- Records the event by changing to 1 the value of the applicable Status Register bit: ERM\_SRx[NCEn]
- Records the corresponding access address that initiated the event in the Memory  $n$  Error Address Register: ERM\_EAR $n$
- Stores the corresponding ECC syndrome in the Memory  $n$  Error Syndrome Register: ERM\_SYN $n$ 
  - In the event of a non-correctable address bit inversion, ERM\_SYN $n$  identifies the pertinent address bit position.
  - In the event of a non-correctable, multi-bit data inversion, the syndrome value does not provide any additional diagnostic information.

The ERM holds event information only for the last reported event.

To clear the record of an event, write 1 to ERM\_SRx[NCEn] to change its value to 0.

### 18.4.2.1 Optional interrupt notification for non-correctable error events

The ERM provides an option to generate an interrupt notification upon the report of a non-correctable ECC event. This sequence describes how to use the option:

1. To enable interrupt notifications for non-correctable error events on Memory  $n$ , set `ERM_CRx[ENCIE $n$ ]` to 1.
2. Subsequently, when a non-correctable error event on Memory  $n$  is detected, the ERM:
  - Records the event and address and stores the ECC syndrome as usual
  - Additionally sends an interrupt notification corresponding to the event
3. To clear both the record of an event and the corresponding interrupt notification, write 1 to `ERM_SRx[NCE $n$ ]` to change its value to 0.

## 18.5 Initialization

For each ERM channel, prepare the corresponding memory array before enabling ERM interrupts about errors for that memory.

1. Initialize the memory to a known value so that the correct corresponding ECC codeword is stored.
2. During the memory's initialization, if the ERM captures information about any ECC error event, clear the corresponding `ERM_SRx[SBC $n$ ]` or `ERM_SRx[NCE $n$ ]` field that stores the record of the event.
3. Program the applicable `ERM_CRx[ESCI $n$ ]` and `ERM_CRx[ENCIE $n$ ]` fields to enable ERM interrupts as desired.

# Chapter 19

## Clocking

### 19.1 Introduction

This chapter describes the architecture for the system level clocks and includes the following information:

- System clock specifics
- Clock architecture
- Clock sources
- Clock monitoring
- Programmable clock dividers
- Clock control registers

The clock architecture of this device contains two clock domains coming from separate PLLs. The first one is the system clock for the cores, cross-bar switch, peripheral bridges, memories, debug logic and memory mapped portion of peripherals. The second one feeds the state machines and protocol engines of communication and timer peripheral modules. These two clock domains can be configured to be completely asynchronous between each other. The PLL generating the system clock (PLL1) can be configured to be frequency modulated to reduce electromagnetic emissions. The PLL generating the peripheral clock (PLL0) cannot be modulated. It is intended to provide an accurate reference clock for peripheral timer and communication functions that cannot tolerate frequency modulation.

The reference clock for PLL0 (non-FM) may come from the following possible sources:

- Crystal oscillator (XOSC)
- External clock (when XOSC is bypassed)
- Internal 16 MHz RC oscillator (IRC)

The reference clock for PLL1 (FM-modulated) may come from the following possible sources:

- Crystal oscillator (XOSC)
- External clock (when XOSC is bypassed)
- Output of PLL0

Out of reset, both clock domains (system and peripheral) are sourced directly from the IRC. After reset, software can select the PLLs or other clock sources (XOSC, external) to connect to system and peripheral clocks. A Progressive Clock Frequency Switch (PCFS) module is available after the system clock selector to allow gradual frequency changes that minimize transient currents. Clock Monitor Units (CMUs) are connected to outputs of clock dividers to verify that their clock frequencies stay within necessary operating limits. When an issue with a clock is found, the CMU sends a failure signal directly to the FCCU.

## **19.2 Clock generation**

The top-level clock generation architecture can be seen in the figure below. All clock selectors and dividers are located and programmed in memory mapped registers of the SIU.

Notes: 1. The clock divider range in the PLL outputs (phi) is non-contiguous in by-2 steps: [2, 4, ..., 124, 126].

2. Divider values and mux selectors are located in SIU registers:  
SIU\_SYSDIV, SIU\_SDCLKCFG, SIU\_LFCLKCFG, SIU\_PSCLKCFG

Figure 19-1. Clock generation diagram

## 19.3 SIU registers

The following table shows the relationship between the clocks of the clock generation diagram and the SIU registers.

Table 19-1. Relationship between clocks and SIU registers

| Clock    | Clock destination          | Clock selector       | Clock divider        | CMU                |
|----------|----------------------------|----------------------|----------------------|--------------------|
| PLL0     | PLL0 input                 | SIU_SYSDIV.PLL0SEL   | Internal to PLL0     |                    |
| PLL1     | PLL1 input                 | SIU_SYSDIV.PLL1SEL   | Internal to PLL1     |                    |
| core_clk | Core0, Core1, Checker Core | SIU_SYSDIV.SYSCLKSEL | SIU_SYSDIV.SYSCLKDIV | CMU_1 <sup>1</sup> |

Table continues on the next page...

**Table 19-1. Relationship between clocks and SIU registers (continued)**

| Clock      | Clock destination                                                                       | Clock selector       | Clock divider         | CMU                |
|------------|-----------------------------------------------------------------------------------------|----------------------|-----------------------|--------------------|
| plat_clk   | Platform modules: Cross-Bar, Peripheral Bridges, Memories, DMA, Flash Controller, Debug |                      | Fixed at divided-by-2 | CMU_2 <sup>1</sup> |
| fm_per_clk | Memory mapped registers of peripherals                                                  |                      | SIUSYSDIV.FMPERDIV    | CMU_3              |
| per_clk    | Protocol and communication engines of peripherals                                       | SIU_SYSDIV.PERCLKSEL | SIU_SYSDIV.PERDIV     | CMU_5              |
| etpu_clk   | eTPU A/B/C                                                                              |                      | SIU_SYSDIV.ETPUDIV    | CMU_4              |
| sd_clk     | Sigma-Delta ADC                                                                         |                      | SIU_SDCLKCFG.SDDIV    | CMU_6              |
| MCAN       | MCAN Protocol Engine Clock                                                              | SIU_SYSDIV.MCANSEL   | Internal to MCAN      |                    |
| eng_clk    | Engineering clock pin                                                                   | SIU_ECCR.ECSS        | SIU_ECCR.ENGDIV       |                    |

1. CMU\_1 and CMU\_2 are physically connected to clock tree spots inside the checker core lake.

## 19.4 Operating frequencies

The device supports the maximum operating frequencies given in the following table.

**Table 19-2. Maximum system and peripheral clock frequencies**

| Clock domain                                        | Mode   | Core (CORE_CLK)  | eTPU (eTPU_CLK)  | Platform (PLAT_CLK) | Peripherals memory mapped registers (FM_PER_CLK) | Peripherals protocol engines (PER_CLK) |
|-----------------------------------------------------|--------|------------------|------------------|---------------------|--------------------------------------------------|----------------------------------------|
| Backwards compatible: one clock domain <sup>1</sup> | Double | 264 <sup>2</sup> | 132 <sup>3</sup> | 132 <sup>3</sup>    | 132 <sup>3</sup>                                 | 132 <sup>3</sup>                       |
|                                                     | eTPU   | 200              | 200              | 100                 | 100                                              | 100                                    |
| Enhanced: dual clock domain <sup>4</sup>            | Normal | 264 <sup>2</sup> | 200              | 132 <sup>3</sup>    | 132 <sup>3</sup>                                 | 100                                    |

1. Clock selectors configured such that all clocks come from a single source, either PLL0 or PLL1.

2. For MPC5775B the value is 220 MHz

3. For MPC5775B the value is 110 MHz

4. Clock selectors configured such that both PLLs drive the clocks into two asynchronous domains.

### NOTE

The essentially asynchronous clock domains of EVTO (eTPU\_CLK) and NPC (CORE\_CLK) require CORE\_CLK to be set to a higher frequency than eTPU\_CLK for guaranteed EVTO capture by NPC. Because CORE\_CLK can be set to FM (2% intentional jitter), the frequency of CORE\_CLK minus 2% must be greater than the frequency of eTPU\_CLK.

## 19.5 Default clock configuration

At power up, the IRC is the default clock for the entire system, with clock selectors configured such that all clocks come from a single clock domain. The default configuration after reset for all clock sources, selectors, and dividers is shown in the tables below.

**Table 19-3. Reset configuration of clock sources**

| Source              | Default after reset                                                                                                                           |
|---------------------|-----------------------------------------------------------------------------------------------------------------------------------------------|
| IRC                 | Always enabled; it is the default clock source.                                                                                               |
| XOSC/External clock | Crystal oscillator and external bypass default state depends on DCF record or configuration pins (see SIU_RSR subsection of the SIU chapter). |
| PLL0                | Disabled and powered down                                                                                                                     |
| PLL1                | Disabled and powered down                                                                                                                     |

**Table 19-4. Reset configuration of clock selectors**

| Selector              | Default after reset |
|-----------------------|---------------------|
| SIU_SYSDIV.PLL0SEL    | Selects XOSC        |
| SIU_SYSDIV.PLL1SEL    | Selects XOSC        |
| SIU_SYSDIV.SYSCLKSEL  | Selects the IRC     |
| SIU_SYSDIV.PERCLKSEL  | Selects core_clk    |
| SIU_LFCLKCFG.LFCLKSEL | Selects the XOSC    |
| SIU_SYSDIV.MCANSEL    | Selects the XOSC    |
| SIU_ECCR.ECSS         | Selects plat_clk    |

**Table 19-5. Reset configuration of clock dividers**

| Divider              | Default after reset |
|----------------------|---------------------|
| SIU_SYSDIV.SYSCLKDIV | Divide-by-1         |
| SIUSYSDIV.FMPERDIV   | Divide-by-2         |
| SIU_SYSDIV.PERDIV    | Divide-by-2         |
| SIU_SYSDIV.ETPUDIV   | Divide-by-2         |
| SIU_SDCLKCFG.SDDIV   | Divide-by-1         |
| SIU_PSCLKCFG.PSDIV   | Divide-by-1         |
| SIU_PSCLKCFG.PSDIV1M | Divide-by-1         |
| SIU_LFCLKCFG.LFDIV   | Divide-by-1         |
| SIU_ECCR.EBDF        | Divide-by-2         |
| SIU_ECCR.ENGDIV      | Divide-by-32        |

## 19.6 Clock sources

This chip has these clock sources:

- 16 MHz Internal RC oscillator (IRC)
- External oscillator (XOSC)
- PLL0 (non-FM PLL)
- PLL1 (FMPLL)

### 19.6.1 16 MHz RC oscillator (IRC)

This device has a 16 MHz internal RC oscillator that is always enabled and cannot be powered down. The IRC can be used as the source of system clock, peripheral clock and PLL clock references. The IRC is the default system and peripheral clock after reset.

The IRC has no dedicated software accessible register interface.

### 19.6.2 External oscillator (XOSC)

The external oscillator (XOSC) provides a clock source for the on-chip PLLs and some peripherals that require accurate clock reference (FlexCAN, MCAN, PIT, PLL, CMU\_0). If required, it can also be used directly as a clock source to the main system and peripheral clocks. The XOSC does not have any software accessible register interface. Configuration is done using DCF records read from UTEST flash memory, which are read by the SSCM during reset and driven to the oscillator. Changing the XOSC configuration requires a reset cycle to take effect.

#### NOTE

The DCF configuration bits for the XOSC have triple-voting flip-flop (TVF) implementation to prevent undetectable errors in the system. See the Device Configuration Format chapter for more information on DCF programming.

#### 19.6.2.1 XOSC configuration

The XOSC has the following configurable features:

- Crystal oscillator can be bypassed to source a clock directly from the EXTAL pin (bypass mode)
- Internal load capacitors can be selected for 20/40 MHz crystal oscillators
- Automatic Loop Control (ALC) can be applied to avoid the need of external series resistor
- Oscillator gain can be selected to match the crystal frequency range

Bypass configuration is controlled by bit 24 of the Miscellaneous DCF record. The selection of internal or external load capacitors on the XTAL/EXTAL pins is determined by bit 25 of the Miscellaneous DCF record. Load capacitor values are determined by the crystal manufacturer data sheet requirements, while accounting for stray PCB and on-chip capacitance. See the device data sheet for on-chip capacitance values.

When using internal load capacitors for the oscillator, the internal capacitance value is configured in the range of 1–16 pF, in approximate steps of 1 pF, by bits 26–30 of the Miscellaneous DCF record. The default value for the trimming bits (0b000000) selects the minimum internal capacitance value (about 1.8 pF).

The XOSC has the ability to be started with a crystal of 8 MHz, 20 MHz, or 40 MHz. Bits 18 and 21 of the Miscellaneous DCF record select which crystal source to use.

Automatic Loop Control (ALC) can be enabled by bit 17 of the Miscellaneous DCF record.

### 19.6.2.2 XOSC startup

During reset, the SSCM reads the XOSC\_CNT field from the Miscellaneous DCF record and pre-loads this value to an internal counter clocked by XOSC. Upon reset exit, the counter counts 512 times XOSC\_CNT. When counting finishes, it means that the XOSC clock is considered to be stable, and a flag called XOSC is set in the SIU\_RSR register. This is a “set-once” bit, which software can check before attempting to use the external oscillator clock source soon after a reset cycle. This flag also enables CMU0 to start monitoring the XOSC clock. From this moment on, if the XTAL clock fails, the SIU\_RSR[XOSC] flag will not be negated to indicate the fail condition, but CMU0 will set a flag and also send an event signal to the FCCU.

### 19.6.3 PLL

This chip has a dual PLL subsystem that provides separate system and peripheral clocks.

The PLLs are disabled after reset. Enable them by software before selecting them as clock sources.

The following image is a block diagram of the dual PLL subsystem.

**Figure 19-2. Dual PLL digital interface block diagram**

### 19.6.3.1 PLL0 (non-FM)

PLL0 is the primary PLL. It provides a non-Frequency Modulated clock to the peripherals and the reference clock to PLL1.

#### 19.6.3.1.1 PLL0 input clocks

The possible input clock sources for PLL0 are the XOSC and IRC. Select the clock reference using multiplexers controlled by the SIU\_SYSDIV register.

#### 19.6.3.1.2 PLL0 output clocks

The output clocks from PLL0 are PHI and PHI1.

- The PHI output clock drives various peripheral clocks and the system clock when PLL1 is not locked or active.
- The PHI1 output provides one of the input references for PLL1.

To generate the reference clock to PLL1, PLL0 has a dedicated output clock divider that is separate from the divider that generates the clock to peripherals.

### 19.6.3.2 PLL1 (FM)

PLL1 is a Frequency Modulated PLL (FMPLL) that is used to drive the system clock.

### 19.6.3.2.1 PLL1 input clocks

The possible input clock sources for PLL1 are PLL0 and the XOSC. Select the clock reference using multiplexers controlled by the SIU\_SYSDIV register.

### 19.6.3.2.2 PLL1 output clocks

The output clock from PLL1 drives the system clock. The PHI output clock contains a fractional divider that can be applied to the loop divide of the PLL to achieve good granularity in the PLL1 PHI output clock frequency.

### 19.6.3.3 PLL register interface

This chip has a single digital interface for both PLLs. The digital interface provides register control of all available features of PLL0 and PLL1.

Before changing any of the dividers or FM configuration, you must force the PLLs into a disabled state by writing 00b to the CLKCFG field of the PLL0CR and PLL1CR registers. This method is the only way to power down the PLLs.

### 19.6.3.4 PLLDIG initialization information

Immediately after reset, PLL0 and PLL1 are disabled. The recommended procedure to program the PLLs and enter normal mode is:

1. Configure PLL0 and related modules.
  - a. With PLL0 disabled, program the desired PLL0 clock source in SIU\_SYSDIV[PLL0SEL]. The default source is XOSC. Write 1 to SIU\_SYSDIV[PLL0SEL] to select IRC as the source.
  - b. Program PLL0DV[PREDIV], PLL0DV[RFDPHI1], PLL0DV[MFD], and PLL0DV[RFDPHI].
  - c. If necessary, modify the CMU frequency meter values (CMU\_MDR and CMU\_FDR) used to monitor the XOSC frequency. The XOSC frequency is compared to the IRCOSC source.
2. Ensure SIU\_RSR[XOSC] is 1 to confirm that XOSC is stable.
3. Turn on PLL0.
  - a. Enable PLL0 by setting PLL0CR[CLKCFG] to 11b.

- b. Poll PLL0SR[LOCK] until its value is 1.
4. Configure PLL1 and related modules.
  - a. With PLL1 disabled, program the PLL1 clock source in SIU\_SYSDIV[PLL1SEL]. The default source is XOSC. Write 1 to SIU\_SYSDIV[PLL1SEL] to select the PHI1 output of PLL0 as the source.
  - b. Program PLL1DV[MFD] and PLL1DV[RFDPHI].
  - c. If required:
    - Program the PLL1FM register with the desired frequency modulation parameters, and
    - Enable FM modulation by setting PLL1FM[MODEN] to 1.

The PLL1FM register must not be written after PLL1 is enabled and operating in normal mode.
5. Turn on PLL1.
  - a. Enable PLL1 by setting PLL1CR[CLKCFG] to 11b.
  - b. Poll PLL1SR[LOCK] until its value is 1.
6. Source the system clock and peripheral clock from the PLLs by programming SIU\_SYSDIV[SYSCLOCKSEL] and SIU\_SYSDIV[PERCLKSEL], respectively.

## 19.7 Clock gating

The SIU\_HLT1 and SIU\_HLT2 registers provide software-controlled clock gating. These registers dispatch request signals to various modules to halt their clock inputs. Modules respond differently to the halt request. The CPU allows its clock inputs to be halted only after the execution of the WAIT instruction. Most other modules wait for internal activities to finish before allowing their clock inputs to be halted by asserting a halt acknowledge signal. A few modules do not implement the stop acknowledge protocol within them and allow their clocks to be halted immediately after the halt request is asserted.

Some peripherals have an internal memory mapped register that can be used to disable the module and to halt the clock input to the module. In most cases the peripheral registers of disabled modules are still readable and writable. However, the halt mechanism of the SIU\_HALT registers disables the read/write functions of the peripheral registers for additional power saving.

When the clocks of all CPUs have been halted and all XBAR masters are idle, then the clocks of the following modules are also halted automatically: XBAR, Peripheral Bridges, system RAM, DMA, STM and Semaphores. The INTC and SWT\_A/SWT\_B clocks are never stopped.

## 19.8 Core and on-platform clocking

The clocks to the cores and on-platform modules come from the FM PLL. The core clock (CORE\_CLK) is double the frequency of the platform clock (PLAT\_CLK), but they are synchronous to each other (same clock domain). The frequency ratio between CORE\_CLK and PLAT\_CLK is fixed at 2:1.

The following modules belong to the core clock domain:

- Core0
- Core1
- Checker core
- Cache memories
- Nexus Port Controller (NPC)

The following modules belong to the platform clock domain:

- System RAM and RAM Controller
- Flash memory and Flash Memory Controller
- Crossbar Switch
- DMA

The frequency modulated peripheral clock (FM\_PER\_CLK) mediates the communication between the Peripheral Bridges and memory-mapped registers within peripheral modules. This clock is part of the same FM clock domain as the core and platform clocks.

## 19.9 Peripheral clocks

Some modules have two clock domains implemented within them. One domain is for the state machines (protocol and/or timing engines) that require accurate non-FM clock sources, and the other domain is for the memory mapped registers that must be accessed by the Peripheral Bridges at the FM clock domain. These modules with separate clock domains can be connected directly to the two FM and non-FM clock sources.

Some other modules, like the eTPU, have a single clock domain with a single clock input.

The following figure depicts all of these cases.

Figure 19-3. Clock distribution

### 19.9.1 eTPU clocking

The eTPUs have a separate clock domain specific to them (ETPU\_CLK), coming from the non-FM PLL. The eTPU clock is synchronous to the other non-FM peripheral clock domain (PER\_CLK), but is asynchronous to the FM-domain clocks (CORE\_CLK, PLAT\_CLK, FM\_PER\_CLK). The reason for a separate clock domain to the eTPUs is to allow them to run at higher speeds than other peripherals, thus optimizing performance and power.

The eTPU module itself has just one clock input that is used by all internal circuits, including timing engines and memory mapped registers. Because this single clock input is connected to the non-FM clock domain, a synchronization gasket mediates communications between the eTPUs and the peripheral bridges, which run at the FM-modulated clock domain. The operation of this gasket is transparent to software.

### 19.9.2 FlexCAN and MCAN clocking

The clock source for the CAN protocol engines can optionally come from the peripheral clock or from the XOSC. For the FlexCAN module, selection of the engine clock source is based on a register field internal to the FlexCAN module. Each FlexCAN instance can select a different source.

For the MCAN modules, selection of the engine clock source is based on the SIU\_SYSDIV[MCANSEL] field. In this case, all MCAN instances receive the same clock.

### 19.9.3 Ethernet clocking

Only an external clock for RMII mode is supported. This chip does not generate an FEC clock internally. The external clock comes from a package pin and goes through the RMII gasket.

#### NOTE

While the FEC is operating, do not change clock configurations (muxes or dividers). Otherwise, FEC transactions in the crossbar might be corrupted.

### 19.9.4 SDADC clocking

The SDADC does not support the use of an external modulator. As a result, the only clock available is the internal clock (`sd_clk`), which is derived from the peripheral (non-FM) clock domain through a clock divider. The division factor for this divider is specified by the `SIU_SDCLKCFG[SDDIV]` field.

### 19.10 Serial boot clocking

Because the IRC is not accurate enough for the serial protocols, prior to entering serial boot mode the BAM switches the clock source to the external oscillator, using either the crystal or external reference—whichever one is effective at startup. No direct signal is available to an external host to indicate that serial boot has been initiated by the BAM.

### 19.11 MCKO

MCKO is an output clock from the Nexus Port Controller (NPC) to the development tools used for the timing of MSEO and MDO pin functions. MCKO is derived from the core clock (`core_clk`), and its frequency is determined by the value of the `MCKO_DIV` field in the port configuration register (PCR) located in the NPC.

### 19.12 CLKOUT / ENGCLK

CLKOUT is a device clock output derived from the platform clock and intended for, but not restricted to, use with the External Bus Interface (EBI). ENGCLK is a 50% duty cycle output clock derived from the platform clock or the crystal oscillator. Both clocks belong to the FM-PLL clock domain, but ENGCLK is not synchronous to CLKOUT (not edge aligned).

The external clock pins CLKOUT and ENGCLK are enabled during and immediately after reset. CLKOUT defaults to the platform clock frequency divided by two, and ENGCLK defaults to the platform clock frequency divided by 32.

### 19.13 Clock monitoring

For all safety-relevant clocks, this chip uses [Clock Monitor Unit \(CMU\)](#) modules to detect a missing clock or incorrect frequency. The IRC and XOSC are used as the clock monitor references.

The chip has nine instances of the CMU module. Each CMU module is programmed independently.

#### 19.13.1 CMU-monitored clocks

The following table shows the clock or clocks monitored by each CMU module instance.

**Table 19-6. CMU-monitored clocks**

| Monitor | Monitored clock(s)                                                                            |
|---------|-----------------------------------------------------------------------------------------------|
| CMU_0   | PLL0, XOSC, IRC                                                                               |

#### 19.13.2 CMU\_0 configuration

CMU\_0 automatically monitors the XOSC clock and is able to monitor PLL0.

The following figure is a block diagram for CMU\_0 on this chip.

Figure 19-4. CMU\_0 block diagram

### 19.13.2.1 CMU\_0 monitoring of XOSC

CMU\_0 is the only CMU instance that monitors the XOSC clock. CMU\_0 uses the IRC clock to measure whether the XOSC clock's frequency is too slow.

CMU\_0's clock monitoring of the XOSC is not controlled by software. Its monitoring of XOSC is always enabled automatically after the SIU\_RSR[XOSC] field indicates that the XOSC clock is stable.

### 19.13.2.2 CMU\_0 monitoring of PLL0

To enable CMU\_0's monitoring of PLL0, the proper initialization sequence is:

1. Configure and enable PLL0.
2. Wait for PLL0 to lock.
3. Enable CMU\_0 for monitoring by setting the CMU\_0\_CSR[CME] field.

### 19.13.3 CMU\_1 to CMU\_8 configuration

For CMU\_1 to CMU\_8:

- Each CMU operates independently from the module that it monitors, with no hardware interlock between them.
- The IRC is the reference clock.

The following figure is a block diagram for CMU\_1 to CMU\_5 on this chip.

**Figure 19-5. CMU\_1 to CMU\_5 block diagram**

The following figure is a block diagram for CMU\_6 to CMU\_8 on this chip.

**Figure 19-6. CMU\_6 to CMU\_8 block diagram**

To enable monitoring of each of CMU\_1 to CMU\_8, the proper initialization sequence is:

1. Enable the clock source corresponding to the particular CMU instance.
2. Ensure that the particular clock source is enabled, stable, and ready to be monitored.
  - If the XOSC is the clock source, then the SIU\_RSR[XOSC] flag must be set.
  - If one of the PLLs is the clock source, then that PLL must be locked.

3. Enable the particular CMU instance for monitoring by setting the applicable CMU<sub>x</sub>\_CSR[CME] field.

### 19.13.4 CMU output signals to FCCU and INTC

The output signals of the CMUs are connected to the FCCU in the following way:

- The OLR output of CMU\_0 is connected to the CMU\_0\_OSC channel of the FCCU.
- The FLC, FHH, and FLL outputs of CMU\_0 are combined (ORed) together and then connected to the CMU\_0\_PLL channel of the FCCU.
- The FLC, FHH, and FLL outputs of CMU\_1 to CMU\_3 are all combined (ORed) together and then connected to the CMU\_COMP channel of the FCCU.
- The FLC, FHH, and FLL outputs of CMU\_4 and the FHH and FLL outputs of CMU\_5 to CMU\_8 are all combined (ORed) together and then connected to the CMU\_OTHER channel of the FCCU.

The output signals of the CMUs are also connected to the INTC in the following way:

- All outputs from CMU\_0 and CMU\_1 are combined (ORed) together and then connected to interrupt vector 350.
- All outputs from CMU\_2 and CMU\_3 are combined (ORed) together and then connected to interrupt vector 351.
- All outputs from CMU\_4 and CMU\_5 are combined (ORed) together and then connected to interrupt vector 352.
- All outputs from CMU\_6 and CMU\_7 are combined (ORed) together and then connected to interrupt vector 353.
- All outputs from CMU\_8 are combined (ORed) together and then connected to interrupt vector 354.

### 19.13.5 CMU register and field availability

[Table 19-7](#) specifies which registers and fields are available on a given CMU for this device.

**Table 19-7. CMU register and field availability**

| Address offset | Register   | CMU   | Note                                                                                                                                                                                            |
|----------------|------------|-------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0x0000         | CMU_CSR    | All   | The SFM, CKSEL1, and RCDIV fields are in CMU_0_CSR only.                                                                                                                                        |
| 0x0004         | CMU_FDR    | CMU_0 | —                                                                                                                                                                                               |
| 0x0008         | CMU_HFREFR | All   | —                                                                                                                                                                                               |
| 0x000C         | CMU_LFREFR | All   | —                                                                                                                                                                                               |
| 0x0010         | CMU_ISR    | All   | The OLRI field is in CMU_0_ISR only. The FLCI field is available in ISR for CMU_0 to CMU_5 and not available in ISR CMU_6 to CMU_8. The FHHI and FLLI fields are available in ISR for all CMUs. |
| 0x0014         | Reserved   | —     | —                                                                                                                                                                                               |
| 0x0018         | CMU_MDR    | CMU_0 | —                                                                                                                                                                                               |

### 19.13.6 CMU\_0\_CSR reset value

The chip-specific reset value of CMU\_0\_CSR is 0000\_0000h.

The reset value of CSR for all other CMU instances, and the reset value of other registers for all CMU instances, appear in the CMU's [Register description and memory map](#).

### 19.13.7 CMU use restrictions

The following restrictions apply to CMU use:

- In CMU\_0,  $f_{\text{CLKMN0\_RMT}}$  must be greater than  $f_{\text{CLKMT0\_RMN}} / 2^{\text{RCDIV}}$  by at least 0.5 MHz to guarantee correct CLKMN0\_RMT monitoring. In CMU\_1 to CMU\_5,  $f_{\text{CLKMN1}}$  must be greater than  $f_{\text{CLKMT0\_RMN}} / 4$  by at least 0.5 MHz to guarantee correct CLKMN1 monitoring. The accuracy of CLKMT0\_RMN (IRC) is specified in the chip's Data Sheet.
- If the checker core and RCCU are disabled (via a DCF client), then the clock to the checker core lake is halted to save power. Because CMU\_1 and CMU\_2 are monitoring points in the clock tree inside the checker core lake, these CMUs cannot be used if the checker core is disabled.

### 19.13.8 Loss-of-clock behavior

Loss-of-clock detection is provided by the FLC output signals of the CMUs; see [Figure 19-4](#) and [Figure 19-5](#). The FLC output signals are combined with other CMU output signals and then routed to the FCCU, as explained in [CMU output signals to FCCU and INTC](#). The FCCU can be programmed to react to CMU failures with a system reset.

Because the FCCU is clocked by the IRC, it can generate the reset request even in the absence of the system clock. The reset signal generated by the FCCU overwrites the system clock selection from SIU\_SYSDIV[SYSCLKSEL], forcing the selection of the IRC as the clock source. This mechanism guarantees that the reset state machine continues to receive a (running) clock so that it can propagate the reset request generated by the FCCU.

### NOTE

CMU\_6 to CMU\_8 monitor clocks whose frequency can be lower than the IRC frequency divided by 4, so they do not implement the FLC detection. The other signals (FLL, FHH) do not assert when the monitored clock stops. Therefore these CMUs cannot detect a loss-of-clock condition.

## 19.14 PLL loss of lock interrupt

Always write 1 to both PLL0CR[LOLIE] and PLL1CR[LOLIE] to keep the loss of lock interrupt function enabled.

The main interrupt functionality is determined by the FCCU via fault input NCF[23] for PLL0 and fault input NCF[24] for PLL1.

## 19.15 Debug mode

The clock generation modules (PLL0, PLL1, XOSC, and IRC) and clock monitoring units (CMUs) do not support entry into debug mode. Therefore, there is no possibility of freezing these modules in debug mode.

## Chapter 20

# Progressive Clock Switch (PCS)

### 20.1 Introduction

This chip contains a Progressive Clock Switch (PCS) module that can be used to prevent sudden voltage drops and overshoots when the system clock frequency is switched from one clock source to another.

### 20.2 Block diagram

The following figure is a block diagram of the PCS system.

**Figure 20-1. PCS system**

### 20.3 Features

The PCS module provides the following features:

- Progressive frequency switching to minimize power supply voltage drops and overshoots
- Clock switching done in two steps: ramp-down from source frequency to IRC frequency, then ramp-up to target frequency
- Fully programmable ramp-down and ramp-up characteristics
- Automatic monitoring of changes on clock switch selector to trigger progressive clock switching feature

## 20.4 Memory map and register definition

Before programming the PCS registers (PCS\_SDUR, PCS\_DIVC $n$ , PCS\_DIVE $n$ , and PCS\_DIVS $n$ ), select IRC as the system clock: ensure SIU\_SYSDIV[SYSCLKSEL] is 00b. This selection preserves reliable progressive clock operation if, during the PCS register programming, a reset event occurs.

Any access to unused registers and write accesses to read-only registers:

- do not change register content
- cause a transfer error

Unless otherwise noted, all registers may be accessed as 32-bit words, 16-bit half-words, or 8-bit bytes. The byte order is big-endian. For example, the PCS\_DIVC1 register's RATE field may be accessed as a word at address offset 704h, as a half-word at address offset 706h, or as a byte at address offset 707h.

**PCS memory map**

| Address offset (hex) | Register name                                    | Width (in bits) | Access | Reset value | Section/ page               |
|----------------------|--------------------------------------------------|-----------------|--------|-------------|-----------------------------|
| 700                  | PCS Switch Duration Register (PCS_SDUR)          | 32              | R/W    | 0000_0000h  | <a href="#">20.4.1/779</a>  |

### 20.4.1 PCS Switch Duration Register (PCS\_SDUR)

This register contains the progressive system clock switching duration for each step.

Address: 0h base + 700h offset = 700h

|       |      |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
|-------|------|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|
| Bit   | 0    | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15 | 16 | 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28 | 29 | 30 | 31 |
| R     | SDUR |   |   |   |   |   |   |   | 0 |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| W     |      |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| Reset | 0    | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0 | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  | 0  |

#### PCS\_SDUR field descriptions

| Field            | Description                                                                                             |
|------------------|---------------------------------------------------------------------------------------------------------|
| 0–7<br>SDUR      | Switch Duration<br>This value defines the duration of one PCS clock switch step in terms of IRC cycles. |
| 8–31<br>Reserved | This field is reserved.<br>This read-only field is reserved and always has the value 0.                 |

### 20.4.2 PCS Divider Change Register for XOSC (PCS\_DIVC1)

This register defines the rate of frequency change and initial change value for the progressive system clock switching when switching the system clock source to or from the crystal oscillator XOSC on ramp-up and ramp-down, respectively.

#### NOTE

Byte write accesses are not allowed for the INIT field of this register. Such an access will not result in an exception, but the value will not be loaded with the new value.

Address: 0h base + 704h offset = 704h

|       |      |   |   |   |   |   |   |   |   |   |    |    |    |    |    |    |    |    |    |    |    |    |    |      |    |    |    |    |    |    |    |    |

## 20.5 Functional description

The progressive clock switch feature is enabled by setting SIU\_SYSDIV[PCSEN]. If PCSEN is set and a change to SIU\_SYSDIV[SYSCLKSEL] is detected by the PCS interface logic (see the PCS block diagram), then a progressive clock switch operation is triggered in the PCS block. The following rules govern the operation:

- If the switching is from the IRC clock, then a ramp-up command is sent to the PCS.
- If switching is to the IRC clock, then a ramp-down command is sent to the PCS.
- If the switching is between two clock sources and neither one is the IRC, then ramp-down and ramp-up commands are simultaneously sent to the PCS.

When the PCS block receives ramp-up and a ramp-down commands simultaneously, it executes the processes in this sequence:

1. Ramp-down process
2. Ramp-up process

During ramp-down, the rate of the frequency change is based on the PCS\_SDUR, PCS\_DIVC $n$ , and PCS\_DIVE $n$  registers, where  $n$  corresponds to the current system clock source selection. During ramp-up, the rate of the frequency change is based on the PCS\_SDUR, PCS\_DIVC $n$ , and PCS\_DIVS $n$  registers, where  $n$  corresponds to the target system clock source selection.

### NOTE

The progressive clock switching feature assumes that the IRC has the lowest clock frequency of the device. Do not attempt to use PCS when switching to or from a frequency that is less than than the IRC frequency.

When the PCS feature is enabled, the PCS module itself—not the SIU\_SYSDIV[SYSCLKSEL] field—controls the selection of the clock source.

While a PCS switching process is in progress:

- The clock source selected by the PCS may differ from the one requested by SIU\_SYSDIV[SYSCLKSEL].

- If software writes a new value to SIU\_SYSDIV[SYSCLKSEL] that corresponds to a clock source different from the one at the start of the switching process, the new value is ignored until the PCS process finishes.
- If software writes a SIU\_SYSDIV[SYSCLKSEL] value corresponding to the same clock source that was in effect at the start of the switching process, the PCS process aborts and returns to that original clock source.

At the end of the clock switching process:

- The SIU\_PCSIFR[PCSI] flag is asserted in the SIU. An interrupt to the CPU is generated if enabled by SIU\_PCSE[PCSE].
- The SIU\_PCSIFR[PCSMS] field indicates the current clock source selected by the PCS. Software can read PCSMS to learn whether or not the PCS switching process succeeded.

If the PCS switching fails (for example, due to incorrect programming), the clock source will not switch to a different one requested by SIU\_SYSDIV[SYSCLKSEL]. Instead, the clock source remains the one selected at the beginning of the attempted PCS switch.

### 20.5.1 Generic clock change requirements

For a maximum allowed change of the frequency ( $f_{\text{chg}}$ ) and for a given source clock frequency  $f_{\text{src}}$  (current or target clock source), the following equation gives the maximum allowed frequency change rate  $a_{\text{max}}$ .

$$a_{\text{max}} = \frac{f_{\text{chg}}}{f_{\text{src}}}$$

### 20.5.2 Configuration of PCS\_SDUR

The switch duration field PCS\_SDUR[SDUR] defines the duration of one system clock switch step in terms of the IRC clock period. After the expiration of this time, the module changes the clock divider value, which changes the frequency of the system clock.

### 20.5.3 Configuration of PCS\_DIVCn[RATE]

For a given maximum allowed frequency change rate  $a_{\text{max}}$ , the following table shows the value  $d$  based on the value programmed into the PCS\_DIVCn[RATE] register.

**Table 20-12. PCS\_DIVCn[RATE] values**

| $a_{\max}$ | $d$   | PCS_DIVCn[RATE] |
|------------|-------|-----------------|
| 0.05       | 0.012 | 12              |
| 0.10       | 0.048 | 48              |
| 0.15       | 0.112 | 112             |
| 0.20       | 0.184 | 184             |

### 20.5.4 Generic clock change properties

The following equation gives the number  $k$  of steps required to ramp down the source frequency ( $f_{\text{src}}$ ) to reach the IRC frequency ( $f_{\text{irc}}$ ).

$$k = \left\lceil 0.5 + \sqrt{0.25 - \frac{2 \left( 1 - \frac{f_{\text{src}}}{f_{\text{irc}}} \right)}{d}} \right\rceil$$

The following equation gives the number  $k$  of steps required to ramp up the IRC frequency ( $f_{\text{irc}}$ ) to reach the target frequency ( $f_{\text{targ}}$ ).

$$k = \left\lceil 0.5 + \sqrt{0.25 - \frac{2 \left( 1 - \frac{f_{\text{targ}}}{f_{\text{irc}}} \right)}{d}} \right\rceil$$

### 20.5.5 Clock ramp-down

The clock ramp-down:

- starts with the divider value 1 and with the given divider increment value PCS\_DIVCn[RATE].
- ends with the given divider value PCS\_DIVE<sub>n</sub>[DIVE].

The following equation gives the divider end value for clock ramp-down.

$$\text{PCS\_DIVE}_n[\text{DIVE}] = \frac{f_{\text{curr}}}{f_{\text{irc}}} \times 1000 - 1$$

In the equation,  $f_{\text{curr}}$  is the frequency of the currently selected system clock source, and  $f_{\text{irc}}$  is the frequency of the IRC clock.

Figure 20-12. System clock ramp-down timing (k = 6 example)

## 20.5.6 Clock ramp-up

The clock ramp-up:

- starts with the given divider value  $\text{PCS\_DIVSn}[\text{DIVS}]$  and with the given divider decrement value  $\text{PCS\_DIVCn}[\text{INIT}]$ .
- ends with the divider value 1.

The following equation gives the initial divider change start value  $\text{PCS\_DIVCn}[\text{INIT}]$  for system clock ramp-up.

$$\text{PCS\_DIVCn}[\text{INIT}] = d \times k \times 1000$$

In the preceding equation,  $k$  is calculated from the second equation in [Generic clock change properties](#). The following equation gives the divider start value for clock ramp-up.

$$\text{PCS\_DIVSn}[\text{DIVS}] = \left(1 + d^{\frac{k(k+1)}{2}}\right) \times 1000 - 1$$

Figure 20-13. System clock ramp-up timing (k = 6 example)

# Chapter 21

## Dual PLL Digital Interface (PLLDIG)

### 21.1 Chip-specific PLLDIG information

The chip has one instance of the PLLDIG module. It includes two PLLs: PLL0 and PLL1.

For more chip-specific information, see the [Clocking](#) details, especially the [PLL](#) details.

### 21.2 Introduction

The chip provides a user interface and control over the dual PLL system composed of PLL0 and PLL1 analog blocks and the digital interface (PLLDIG). The two analog PLL blocks are cascaded, with the PHI1 output of PLL0 feeding the clock input of PLL1.

A key feature of the dual PLL architecture is the ability to drive peripherals from the PLL0 PHI output, which is non-modulated and independent of the core clock frequency. The core and platform clocks are driven by the PLL1 PHI frequency-modulated output.

### 21.3 Acronyms and Abbreviations

The following table contains sample acronyms and abbreviations used in this chapter.

**Table 21-1. Acronyms and abbreviated terms**

| Term  | Meaning                               |
|-------|---------------------------------------|
| PLL   | Phase Lock Loop                       |
| RFD   | Reduced Frequency Divider             |
| MFD   | Multiplication Factor Divider         |
| VCO   | Voltage Controlled Oscillator         |
| FMPLL | Frequency Modulated Phase Locked Loop |

## 21.4 Block Diagram

Please refer to the “Clocking chapter” of this *Reference Manual* to see the block diagram.

## 21.5 Features

The Dual PLLDIG has the following features:

- Supports dual PLL in cascaded mode with PLL0 clock out as reference clock to PLL1.
- Reference clock pre-divider for finer frequency synthesis resolution.
- Reduced frequency divider for decreasing the PLL0/PLL1 output clock frequency without causing the PLLs to lose lock.
- Programmable frequency modulation on PLL1.
- Lock detect circuitry reports when the PLLs have achieved frequency lock, and continuously monitors lock status to report loss of lock conditions.
  - User-selectable ability to generate an interrupt request upon loss of lock.
  - The loss of lock indication is sent to the FCCU via the system glue logic.

## 21.6 Modes of operation

The operating mode of the PLLs is indicated by the value of PLL $n$ CR[CLKCFG]. The various modes of operation for the PLL are:

- Normal mode with reference, with either PLL0 or both PLLs enabled
- PLL disabled

Normal mode is defined as the mode where the clocks are driven by the PLLs. When using a crystal for the clock reference, reset should remain asserted until the oscillator has stabilized.

### 21.6.1 Normal mode with reference, PLL0 or both PLLs enabled

In normal mode, PLL0 receives an input clock from the reference that can be prescaled by the pre-divider. PLL0 multiplies the frequency to create the PLL0 output clock. The user must supply a crystal that is within the appropriate frequency range, the crystal manufacturer's recommended external support circuitry and short signal route from the MCU to the crystal.

For information about the selection of a clock reference for each PLL, see [PLL](#) in the Clocking details.

PLL0 generates a non-modulated clock which drives PLL0 PHI1. PLL1 can generate a frequency modulated clock or a non-modulated clock (for example, locked on a single frequency). Write the PLL1FM register to program the modulation rate, modulation depth, and whether PLL modulating is enabled.

#### NOTE

PLL1 must be configured to work with a reference clock from PLL0 only after PLL0 has achieved lock.

For proper power sequencing of analog PLL blocks, write to PLL0CR[CLKCFG] before writing to PLL1CR[CLKCFG].

While powering down the PLLs: If PLL0:PHI1 is used as the source for PLL1, power down the PLLs in this sequence to ensure proper shutoff:

1. PLL1
2. PLL0

## 21.7 Memory map and register definition

This section provides the memory map and detailed descriptions of all registers for configuring the PLLs. The table below shows the memory map. Addresses are given as offsets from the module base address. All registers can be accessed using 8-bit, 16-bit or 32-bit addressing.

**PLLDIG memory map**

| Address offset (hex) | Register name                                | Width (in bits) | Access | Reset value | Section/ page              |
|----------------------|----------------------------------------------|-----------------|--------|-------------|----------------------------|
| 0                    | PLLDIG PLL0 Control Register (PLLDIG_PLL0CR) | 32              | R/W    | 0000_0000h  | <a href="#">21.7.1/794</a> |

**21.7.3 PLLDIG\_PLL0 Divider Register (PLLDIG\_PLL0DV)**

The PLL0DV register provides the PHI/PHI1 output clock reduced frequency divider (RFDPHI and RFDPHI1), pre-divider (PREDIV), and loop divider (MFD). If this register's fields are modified without powering down the PLL, the PLL will lose lock and generate either an interrupt or a failure signal to the FCCU, based on which is enabled.

| 28<br>LOLF        | Loss-of-lock flag<br><br>This bit provides the interrupt request flag for the loss-of-lock condition. Software must write 1 to LOLF to clear it to 0; writing 0 has no effect. The flag is set to 1 when the PLL loses lock or when the divider/modulation registers are changed on the fly. This flag bit is sticky in the sense that if lock is reacquired, the bit remains set to 1 until cleared by either writing 1 or asserting reset. The LOLF is not asserted when the PLL is disabled, but disabling the PLL will not automatically clear the LOLF if it was previously asserted while the PLL was in normal mode.<br><br>0 No loss of lock detected. Interrupt service not requested.<br>1 Loss of lock detected. Interrupt service requested. |

## 21.7.6 PLLDIG PLL1 Divider Register (PLLDIG\_PLL1DV)

The PLL1DV register provides the PHI output clock reduced frequency divider (RFDPHI) and loop divider (MFD). If this register's fields are modified without powering down the PLL, the PLL will lose lock and generate either an interrupt or a failure signal to the FCCU, based on which is enabled.

## 21.7.7 PLLDIG PLL1 Frequency Modulation Register (PLLDIG\_PLL1FM)

The PLL1FM register enables frequency modulation on PLL1 and provides controls for the FM spread spectrum, modulation depth, and modulation rate. This register should be written when PLL1CR[CLKCFG] = 00b (PLL1 powered down). After the PLL is on and has locked, changing the values of PLL1FM[MODEN] and PLL1FM[MODSEL] can result in the PLL losing its lock. The PLL would then require power cycling to regain normal functionality.

### 21.7.8 PLLDIG\_PLL1 Fractional Divide Register (PLLDIG\_PLL1FD)

The PLL1FD register provides the enable and fractional divide factor for the loop divider. This register should be written when PLL1CR[CLKCFG] = 00b (PLL1 powered down). After the PLL is running and has locked, changing the value of FDEN can result in the PLL losing its lock. The PLL would then require power cycling to regain normal functionality.

Address: 0h base + 30h offset = 30h

| 20–31<br>FRCDIV   | <p>Fractional divide input</p> <p>When the fractional divide is disabled, the VCO clock frequency is the product of the input clock and the loop divide factor (MFD). When fractional divide is enabled and dither is disabled (DTHDIS1 is 1), the VCO clock frequency is given by:</p> $\text{VCO Frequency} = \text{InputClock} \times (\text{PLL1DV}[\text{MFD}] + (\text{FRCDIV} \div 2^{12}))$ <p>When fractional divide is enabled and dither is enabled (DTHDIS1 is 0), the VCO clock frequency is given by:</p> $\text{VCO Frequency} = \text{InputClock} \times (\text{PLL1DV}[\text{MFD}] + (\text{FRCDIV} \div 2^{12}) + (1 \div 2^{13}))$ <p>In these equations, FRCDIV is the decimal equivalent of the FRCDIV field.</p> |

## 21.8 Functional description

This section explains the operation and configuration of the Dual PLLDIG module.

### 21.8.1 Input clock frequency

PLL0 and PLL1 are designed to operate over an input clock frequency range. The operating ranges for the PLLs are discussed in detail in the *Data Sheet*.

## 21.8.2 Clock configuration

The relationship between input and output frequency is determined by programming the PLL0DV and PLL1DV registers and calculated according to the following equations.

### NOTE

In the following equations, use the programmed value for each register field. For example, when PLL0DV[RFDPHI] is programmed to the value 1, use the value 1 in the equation for that field.

$$f_{\text{pll0\_phi}} = f_{\text{pll0\_ref}} \times \frac{\text{PLL0DV[MFD]}}{\text{PLL0DV[PREDIV]} \times \text{PLL0DV[RFDPHI]}}$$

**Figure 21-9. PLL0 PHI output frequency**

$$f_{\text{pll0\_phi1}} = f_{\text{pll0\_ref}} \times \frac{\text{PLL0DV[MFD]}}{\text{PLL0DV[PREDIV]} \times \text{PLL0DV[RFDPHI1]}}$$

**Figure 21-10. PLL0 PHI1 output frequency**

$$f_{\text{pll1\_phi}} = f_{\text{pll1\_ref}} \times \frac{\text{PLL1DV[MFD]}}{2 \times \text{PLL1DV[RFDPHI]}}$$

**Figure 21-11. PLL1 PHI output frequency (PLLDIG\_PLL1FD[FDEN] = 0)**

$$f_{\text{pll1\_phi}} = f_{\text{pll1\_ref}} \times \left( \frac{\text{PLL1DV[MFD]} + \frac{\text{PLL1FD[FRCDIV]}}{2^{12}} + \frac{1}{2^{13}}}{2 \times \text{PLL1DV[RFDPHI]}} \right)$$

**Figure 21-12. PLL1 PHI output frequency (PLLDIG\_PLL1FD[FDEN] = 1 and PLLDIG\_PLL1FD[DTHDIS1] = 0)**

### NOTE

When PLLDIG\_PLL1FD[FDEN] = 1 and PLLDIG\_PLL1FD[DTHDIS1] = 1, in [Figure 21-12](#) remove from the numerator: + 1/(2<sup>13</sup>)

$$f_{\text{pll1\_phi}} = \frac{f_{\text{pll0\_ref}} \times \text{PLL0DV}[\text{MFD}] \times \text{PLL1DV}[\text{MFD}]}{\text{PLL0DV}[\text{PREDIV}] \times \text{PLL0DV}[\text{RFDPHI1}] \times \text{PLL1DV}[\text{RFDPHI}] \times 2}$$

**Figure 21-13. PLL1 PHI output frequency when PLL0 PHI1 is PLL1 reference (PLLDIG\_PLL1FD[FDEN] = 0)**

$$f_{\text{pll1\_phi}} = \frac{f_{\text{pll0\_ref}} \times \text{PLL0DV}[\text{MFD}] \times (\text{PLL1DV}[\text{MFD}] + \frac{\text{PLL1FD}[\text{FRCDIV}]}{2^{12}} + \frac{1}{2^{13}})}{\text{PLL0DV}[\text{PREDIV}] \times \text{PLL0DV}[\text{RFDPHI1}] \times \text{PLL1DV}[\text{RFDPHI}] \times 2}$$

**Figure 21-14. PLL1 PHI output frequency when PLL0 PHI1 is PLL1 reference (PLLDIG\_PLL1FD[FDEN] = 1 and PLLDIG\_PLL1FD[DTHDIS1] = 0)**

### NOTE

When PLLDIG\_PLL1FD[FDEN] = 1 and PLLDIG\_PLL1FD[DTHDIS1] = 1, in [Figure 21-14](#) remove from the numerator: + 1/(2<sup>13</sup>)

The relationship between the VCO frequency ( $f_{\text{VCO}}$ ) and the output frequency of the PLLs is determined by the value of PLL1DV[RFDPHI], PLL0DV[RFDPHI], and PLL0DV[RFDPHI1], according to the following equations:

$$f_{\text{pll0\_VCO}} = f_{\text{pll0\_phi}} \times 2 \times \text{PLL0DV}[\text{RFDPHI}]$$

$$f_{\text{pll1\_VCO}} = f_{\text{pll1\_phi}} \times 2 \times \text{PLL1DV}[\text{RFDPHI}]$$

$$f_{\text{pll0\_VCO}} = f_{\text{pll0\_phi1}} \times 2 \times \text{PLL0DV}[\text{RFDPHI1}]$$

### NOTE

$f_{\text{pll0\_phi1}}$  is the reference clock generated by PLL0 for PLL1.

When programming the PLLs, user software must not violate the maximum system clock frequency or max/min VCO frequency specification PLL0 and PLL1. Furthermore, the PLL0DV[PREDIV] value must not be set to any value that causes the input frequency to the phase detector of analog PLL blocks to go below the prescribed ranges.

The PLL $n$ SR[LOCK] flag is immediately negated if the fields of PLL $n$ DV are changed without powering down the analog PLLs.

## NOTE

The PLL must be powered down and powered up by writing 00b to the PLL $n$ CR[CLKCFG] fields before PLL0DV[PREDIV], PLL0DV[MFD], PLL1DV[MFD], or the reference input clock values are modified.

The recommended procedure to program the PLLs and engage normal mode appears in [Initialization information](#).

### 21.8.3 Loss of lock

In the event that the PLL loses lock, the PLL digital interface registers provide the flexibility to select whether to generate an interrupt. If an interrupt is asserted, a failure event is also sent to the FCCU.

A loss-of-lock interrupt and FCCU failure event are generated only when the PLL is operating in normal mode. The PLL $n$ SR[LOLF] bits are not asserted when the PLLs are disabled (PLL $n$ CR[CLKCFG]=00b). If an LOLF flag was asserted while the PLL was in normal mode and then the PLL is disabled, the PLL disabling does not automatically clear the flag.

The lock indication from the analog PLL is synchronized and stored in the status register. When the analog PLL loses lock or regains lock, the status register indicates it immediately (after synchronization time).

### 21.8.4 Frequency modulation

Frequency modulation uses a triangular profile as shown in [Figure 21-15](#). The modulation frequency and depth are controlled using PLL1FM[MODPRD] and PLL1FM[INCSTP].

Figure 21-15. Triangular frequency modulation

**NOTE**

The device maximum operating frequency includes the frequency modulation. If center modulation is used, the  $f_{\text{sys}}$  must be below  $f_{\text{max}}$  by MD percentage such that  $f_{\text{max}} = f_{\text{sys}} \times (1 + (\text{MD}\% / 100))$ .

The following equations define how to calculate PLL1FM[MODPRD] and PLL1FM[INCSTP] based on the frequency of the feedback divider ( $f_{\text{ref}}$ ), the modulation frequency ( $f_{\text{mod}}$ ) and the modulation depth percentage (MD).

$$\text{PLL1FM}[\text{MODPRD}] = \text{round} \left( \frac{f_{\text{pll1\_ref}}}{4 \times f_{\text{mod}}} \right)$$

Figure 21-16. PLL1FM[MODPRD] calculation

The equation to determine PLLFM[INCSTP] is shown in [Figure 21-17](#).

$$\text{PLL1FM}[\text{INCSTP}] = \text{round} \left( \frac{(2^{15} - 1) \times \text{MD} \times \text{PLL1DV}[\text{MFD}]}{100 \times 5 \times \text{PLL1FM}[\text{MODPRD}]} \right)$$

Figure 21-17. PLL1FM[INCSTP] calculation

PLL1FM[MODPRD] and PLL1FM[INCSTP] are subject to the following restriction:

$$(\text{PLL1FM}[\text{MODPRD}] \times \text{PLL1FM}[\text{INCSTP}]) < 2^{15}$$

Figure 21-18. PLL1FM[MODPRD] and PLL1FM[INCSTP] restriction

Due to the preceding rounding operations, the effective modulation depth applied to the FMPLL is as shown in [Figure 21-19](#).

$$\text{ModulationDepth} = \text{round} \left( \frac{\text{PLL1FM}[\text{MODPRD}] \times \text{PLL1FM}[\text{INCSTP}] \times 100 \times 5}{(2^{15} - 1) \times \text{PLL1DV}[\text{MFD}]} \right)$$

**Figure 21-19. Modulation Depth**

As an example, suppose the following configuration, in which PLL1DV[RFDPHI] represents the programmed value of that field:

- Input frequency: 40 MHz
- Loop divider (PLL1DV[MFD]): 20
- VCO frequency: 40 MHz × 20 = 800 MHz
- PLL output frequency: 800 MHz / (2 × PLL1DV[RFDPHI])
- Center spread (PLL1FM[MODSEL] = 0)
- Modulation frequency: 100 kHz
- Modulation depth: +/- 2.0% (4% peak-to-peak)
- PLL1FM[MODPRD] = round[(40 × 10<sup>6</sup>) / (4 × 100 × 10<sup>3</sup>)] = round[100.00] = 100
- PLL1FM[INCSTP] = round[((2<sup>15</sup> - 1) × 2 × 20) / (100 × 5 × 100)] = round[26.2136] = 26
- PLL1FM[MODPRD] × PLL1FM[INCSTP] = 100 × 26 = 2600 (which is less than 2<sup>15</sup>)
- MD (quantized) = ((100 × 26 × 100 × 5) / ((2<sup>15</sup> - 1) × 20)) = 1.983703%

In this example, the modulation error is 0.0163%.

The recommended sequence for programming the FM is:

1. Power down PLL1 by writing PLL1CR[CLKCFG] = 00b.
2. Program PLL1FM while PLL1 is powered down.
3. Power up PLL1 by writing PLL1CR[CLKCFG] = 11b.

## 21.9 Maximum lock time

Maximum lock time is for the condition when the operating mode of the PLL has changed from power-down to Normal mode, input control bits are stable, and supplies (analog and digital) have attained levels shown in the *Data Sheet*. It is also the time in which the PLLs regain lock after a loss of lock event, assuming all inputs are stable and supplies are within specifications.

## 21.10 Initialization information

Coming out of reset PLL0 and PLL1 are disabled. The Dual PLLDIG initialization procedure is described in [PLLDIG initialization information](#) in the Clocking details.

## Chapter 22

# Clock Monitor Unit (CMU)

### 22.1 Chip-specific CMU information

The chip has nine instances of the CMU module. Each CMU module is programmed independently.

For more chip-specific information, see [Clock monitoring](#).

### 22.2 Introduction

The Clock Monitor Unit (CMU), also referred to as Clock Quality Checker or Clock Fault Detector, serves three purposes:

- Measures the frequency of clock source CLKMT0\_RMN with CLKMN0\_RMT as the reference clock
- Monitors CLKMN0\_RMT frequency with CLKMT0\_RMN as reference clock
- Monitors CLKMN1 frequency with CLKMT0\_RMN as reference clock and detects if the monitored clock frequency leaves an upper or lower frequency boundary

#### NOTE

See the "Clocking" chapter for chip-specific sources used by the CMU.

One of the tasks is to supervise the integrity of the various clock sources on the chip, for example CLKMN0\_RMT or CLKMN1. If the monitored clock frequency is less than the reference clock, or it violates an upper or lower frequency boundary, the CMU detects and reports this event. These events signal the FCCU, which can take the necessary corrective actions as its configuration dictates.

The CMU can monitor CLKMN0\_RMT, which must have a frequency higher than that of CLKMT0\_RMN divided by the factor shown in CMU\_CSR[RCDIV], and reports this event. The CMU can also monitor CLKMN1 and generate an event if CLKMN1 is greater than a high frequency boundary or less than a low frequency boundary. The upper and lower frequency boundaries are defined by the CMU High Frequency Reference Register (CMU\_HFREFR) and CMU Low Frequency Reference Register (CMU\_LFREFR).

The second task of the CMU is to provide a frequency meter, which allows measuring the frequency of a clock source against a reference clock. This is useful to correct/calculate the time deviation of a counter that is clocked by the metered clocks.

### **NOTE**

See the "Clocking" chapter for the number of CMU instances on this chip.

## **22.2.1 Main features**

- CLKMT0\_RMN frequency measurement with CLKMN0\_RMT as reference clock.
- CLKMN0\_RMT monitoring with respect to  $\text{CLKMT0\_RMN} \div 2^{\text{CSR[RCDIV]}}$  clock.
- Upper or lower frequency boundary monitoring of CLKMN1 with respect to  $\text{CLKMT0\_RMN} \div 4$ .
- Event generation for various failures detected inside monitoring unit.

## **22.3 Block diagram**

The block diagram of the CMU module(s) is shown in the "Clocking" chapter of this Reference Manual.

## **22.4 Signals**

The table below describes the signals on the boundary of the CMU (in alphabetical order).

**Table 22-1. Signal description**

| Signal     | I/O | Description                                                                                                                                                                                                                                                                                                  |
|------------|-----|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| CLKMNO_RMT | I   | Monitored Clock Signal 0/Metered Clock Signal Reference — Receives a clock signal that the CMU compares to a specified low-limit frequency to determine whether the frequency of the clock signal is greater than the specified limit. Also provides a reference clock signal for all metered clock signals. |
| CLKMN1     | I   | Monitored Clock Signal 1 — Receives a clock signal that the CMU compares to specified low-limit and high-limit frequencies to determine whether the frequency of the clock signal is between the specified limits.                                                                                           |
| CLKMT0_RMN | I   | Metered Clock Signal 0/Monitored Clock Signal Reference — Receives a clock signal that the CMU measures against a reference clock frequency. Also provides a reference clock signal for all monitored clock signals.                                                                                         |

**NOTE**

See the "Clocking" chapter for device specific clock sources of each CMU.

## 22.5 Register description and memory map

This section describes in address order all the CMU registers. Each description includes a standard register diagram with an associated figure number. The CMU memory map is listed in the following table.

**NOTE**

See "Clocking" chapter for register and field availability details.

**CMU memory map**

| Address offset (hex) | Register name                                             | Width (in bits) | Access | Reset value                 | Section/ page              |
|----------------------|-----------------------------------------------------------|-----------------|--------|-----------------------------|----------------------------|
| 0                    | CMU Control Status Register (CMU_CSR)                     | 32              | R/W    | <a href="#">See section</a> | <a href="#">22.5.1/814</a> |

**22.5.2 CMU Frequency Display Register (CMU\_FDR)**

The CMU\_FDR is used to determine the measured frequency of:

- CLKMT0\_RMN

with respect to the reference clock CLKMN0\_RMT.

**NOTE**

The CMU\_FDR should be read only when  
CMU\_CSR[SFM] = 0.

Address: 0h base + 4h offset = 4h

| 12–31<br>FD      | <p>Measured frequency bits.</p> <p>This register displays the measured frequency (<math>f_{\text{sel}}</math>) with respect to the reference clock (<math>f_{\text{CLKMN0\_RMT}}</math>). The measured value is given by the following formula:</p> $f_{\text{sel}} = (f_{\text{CLKMN0\_RMT}} \times \text{CMU\_MDR[MD]}) \div \text{CMU\_FDR[FD]}$ |

### 22.5.3 CMU High Frequency Reference Register CLKMN1 (CMU\_HFREFR)

The HFREFR is configured for the high frequency reference that the CMU will use for comparing against the monitored clock. The figure and table below show the CMU\_HFREFR register.

#### NOTE

For correct synchronization of CMU\_HFREFR write data, the user must ensure that a time interval of 10 peripheral bus clock cycles + 40 CLKMT0\_RMN clock cycles elapses before attempting subsequent writes to the same register.

#### CMU\_HFREFR field descriptions

| Field            | Description                                                                                                                                                                                                   |
|------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–19<br>Reserved | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                       |
| 20–31<br>HFREF   | High Frequency reference value.<br>These bits determine the high reference value for the CLKMN1 frequency. The reference value is given by: $(\text{HFREF} \div 16) \times (f_{\text{CLKMT0\_RMN}} \div 4)$ . |

### 22.5.4 CMU Low Frequency Reference Register CLKMN1 (CMU\_LFREFR)

The LFREFR is configured for the low frequency reference that the CMU will use for comparing against the monitored clock. The figure and table below show the CMU\_LFREFR register.

#### NOTE

For correct synchronization of CMU\_LFREFR write data, the user must ensure that a time interval of 10 peripheral bus clock cycles + 40 CLKMT0\_RMN clock cycles elapses before attempting subsequent writes to the same register.

Address: 0h base + Ch offset = Ch

| 20–31<br>LFREF   | Low Frequency reference value.<br><br>These bits determine the low reference value for the CLKMN1 frequency. The reference value is given by:<br>$(\text{LFREF} \div 16) \times (f_{\text{CLKMT0\_RMN}} \div 4)$ . |

**22.5.5 CMU Interrupt Status Register (CMU\_ISR)****NOTE**

All flags in the CMU\_ISR are set asynchronously. This register must be read only after a CMU event is triggered. Otherwise, a read access on this register may fetch an incorrect value (see "Clocking" chapter for interrupt operation) .

**NOTE**

Before entering low-power stop modes, all clock frequency measurements in the CMU should be disabled. Failing to do so may result in ISR flags being spuriously set.

Address: 0h base + 10h offset = 10h

## 22.6 Functional description

### 22.6.1 Frequency meter

The purpose of the frequency meter is to evaluate the deviation from the nominal metered source (such as CLKMT0\_RMN) frequencies. Programming of the CMU\_CSR[CKSEL1] field is used to select one of the metered clocks from a multiplexer that drives a simple Frequency Meter (see the CMU Block Diagram in the "Clocking" chapter). The reference clock for the Frequency Meter is the CLKMN0\_RMT signal. The measurement starts when CMU\_CSR[SFM] = 1. The measurement duration is given by the contents of CMU\_MDR[MD] in terms of number of clock cycles of the selected metered clock. The CMU\_CSR[SFM] bit is cleared by hardware once the frequency measurement is complete and the count is loaded in CMU\_FDR[FD]. The frequency of the selected clock ( $f_{sel}$ ) can be derived from the value loaded in the CMU\_FDR[FD] as shown in the following equation:

$$f_{sel} = (f_{CLKMN0\_RMT} \times MDR[MD]) / FDR[FD]$$

### 22.6.2 CLKMN0\_RMT supervisor

If frequency of CLKMN0\_RMT is smaller than the frequency of CLKMT0\_RMN  $\div 2^{CMU\_CSR[RCDIV]}$  and CLKMN0\_RMT is 'ON', then:

- The CMU writes 1 to CMU\_ISR[OLRI].
- The CMU asserts the OLR signal.

**NOTE**

The equation below must be taken into consideration to guarantee correct  $f_{\text{CLKMN0\_RMT}}$  monitoring.

$$f_{\text{CLKMN0\_RMT}} \geq \frac{1.25 \times f_{\text{CLKMT0\_RMN}}}{2^{\text{CMU\_CSR[RCDIV]}}}$$

**Equation 1. Timing requirement****22.6.3 CLKMN1 supervisor**

The frequency of CLKMN1 ( $f_{\text{CLKMN1}}$ ) can be monitored by programming CMU\_CSR[CME] = 1. CLKMN1 monitoring starts as soon as CMU\_CSR[CME] = 1. This monitor can be disabled at any time by programming CMU\_CSR[CME] = 0.

If  $f_{\text{CLKMN1}}$  is greater than the reference value determined by fields CMU\_HFREFR[HFREF] and CLKMN1 is 'ON', then:

- The CMU writes 1 to CMU\_ISR[FHHI].
- The CMU asserts the FHH signal.

If  $f_{\text{CLKMN1}}$  is less than a reference clock frequency ( $f_{\text{CLKMT0\_RMN}} \div 4$ ) and the CLKMN1 is 'ON', then:

- The CMU writes 1 to CMU\_ISR[FLCI].
- The CMU asserts the FLC signal.

If  $f_{\text{CLKMN1}}$  is less than a reference value determined by the bits CMU\_LFREFR[LFREF] and the CLKMN1 is 'ON', then:

- The CMU writes 1 to CMU\_ISR[FLLI].
- The CMU asserts the FLL signal.

**Note**

$f_{\text{CLKMN1}}$  must be greater than  $f_{\text{CLKMT0\_RMN}} \div 4$  by at least 0.5 MHz in order to guarantee correct CLKMN1 monitoring.

An example of determining the  $\text{HFREF}_{\text{Actual}}$  is as follows. Assume a  $f_{\text{CLKMT0\_RMN}} = 16$  MHz with a accuracy of  $\pm 5\%$  (see *Data Sheet* for actual value). In order to monitor a  $f_{\text{CLKMN1}} = 200$  MHz, the ideal  $\text{HFREF}_{\text{Ideal}} = 800$ . The actual HFREF value will be 842 when the accuracy is taken into

consideration ( $\text{HFREF}_{\text{Actual}} = (\text{HFREF}_{\text{Ideal}} \div 0.95)$ ). The actual LFREF value will be 762 when accuracy is taken into consideration ( $\text{LFREF}_{\text{Actual}} = \text{LFREF}_{\text{Ideal}} \div 1.05$ ).

# Chapter 23

## Embedded Memories

### 23.1 Overview

This chip's features of embedded memory include:

- On-chip SRAM, including system SRAM and local instruction and data caches for each processor core
- On-chip system error correction code (ECC) flash memory
- End-to-end ECC (e2eECC) error detection and correction (not all modules support e2eECC)
- Embedded memories in select peripherals, including:
  - FlexCAN
  - M\_CAN
  - eDMA
  - FEC
  - eTPU
  - CSE

For more information about embedded memory in a peripheral, see the peripheral's dedicated chapter.

### 23.2 End-to-end Error Correction Code (e2eECC)

To support market requirements related to improved functional and transient fault detection capabilities, this chip includes end-to-end ECC (e2eECC) support. This e2eECC is structurally different from traditional "ECC at memory" functionality because

it provides robust error detection capabilities from one endpoint of an information transfer to another endpoint, with temporary information storage in one or more intermediate components.

Memory protected by ECC/EDC traditionally generates and checks additional error parity information local to the memory unit to detect and/or correct errors that have occurred on data stored in the memory. In contrast, e2eECC generates error protection codes at the source of data generation. It sends the encoded data and error protection codes to intermediate storage when a memory write is initiated by a bus master, and it performs a data integrity check using the previously stored error protection codes at a data memory when a read of stored information is requested by a bus master. Depending on the particular memory unit, the intermediate storage may transform the generated error protection codes into another format for storage and then regenerate the codes for provision when a request is made to read the stored information, or it may simply store the original protection codes unaltered.

To protect additional information associated with an access, the error protection codes are generated on the basis of more than the data associated with a storage location. In particular, address information corresponding to the access location of the stored information is combined with the stored data at the data source to generate error protection codes that cover certain types of addressing errors in the system interconnection or in the memory unit. The error protection codes may be checked at the memory unit on a store operation to ensure that no address information or data has been corrupted while the request has transitioned through the device from the bus master source. The memory unit may simply store the received data and protection codes at the address it receives, or it may check the error protection codes to ensure that address decoding within the storage memory was performed properly (although not all address decoding errors can be detected this way).

On a read request from a bus master, the memory unit retrieves the data information and error protection codes corresponding to the received address from the storage location or locations and supplies the data along with the error protection codes to the requesting device. The requesting device uses a locally stored address value corresponding to the read request to check the returning data and error protection codes to ensure that no errors have occurred in either addressing the memory or in the retrieved data. This approach ensures that the address sent for the request was not corrupted, the addressed location was actually accessed (to the extent it is possible to ensure), and the stored data was error free, to the extent the ECC coding scheme is able to detect. As a result, the fault coverage provided by the end-to-end check is considerably more robust than the previous implementation of locally generated and checked/corrected error protection at each memory unit.

The following table compares the traditional and e2eECC approaches.

**Table 23-1. ECC comparison of data write-then-read sequence**

| Traditional ECC                                                                                                                                                                                                                     | End-to-end ECC (e2eECC)                                                                                                                                                                                           |
|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Bus master initiates data write                                                                                                                                                                                                     | Bus master initiates data write and generates ECC checkbits based on 29-bit address and 64-bit data fields for the computational shell, or based on 30-bit address and 32-bit data field for the peripheral shell |
| Data write transfer routed from bus master to appropriate bus slave                                                                                                                                                                 | Data write transfer (including checkbits) routed from bus master to appropriate bus slave                                                                                                                         |
| For a bus memory slave, generate the ECC checkbits based on the data value and store data + checkbits into the memory                                                                                                               | For a bus memory slave, store data and checkbits into the memory                                                                                                                                                  |
| Bus master initiates data read of previously written memory location                                                                                                                                                                | Bus master initiates data read of previously written memory location                                                                                                                                              |
| Data read transfer routed from bus master to appropriate bus slave                                                                                                                                                                  | Data read transfer routed from bus master to appropriate bus slave                                                                                                                                                |
| For a bus memory slave, the memory array is accessed, the controller performs the ECC checkbit decode and syndrome generation, performs any needed single-bit correction, and drives the read data onto the system bus interconnect | For a bus memory slave, the memory array is accessed, and the controller passes the read data and associated checkbits onto the system bus interconnection                                                        |
| The bus master captures the read data and continues                                                                                                                                                                                 | The bus master captures the read data and associated checkbits, performs the ECC checkbit decode and syndrome generation, performs any needed single-bit correction, and continues                                |

The scope of differences in the operations "covered" by the ECC checks is readily apparent with the e2eECC concept, improving fault detection capabilities in two important aspects:

- The entire data transaction—from the initiating bus master, through the entire platform crossbar steering mechanism, to the destination slave target—is covered during write accesses. Likewise, a read is checked from the initiating bus master, through the crossbar steering mechanism, through the actual memory read and transmission of the data and checkbits back to the bus master, where the integrity and correctness of the entire transaction is checked.
- The selected ECC protects both the address field and the data field.

### NOTE

Compared to MPC5676R: For every SRAM and DMA transfer initiation, e2eECC on MPC5775E requires 2 additional clock cycles. The performance impact of these additional clocks can be reduced through the use of bursting.

In general, e2eECC improves implementation. The traditional ECC approach places the checkbit decode and error syndrome generation with the error/no\_error state, affecting whether the system bus transfer must be stalled (to correct a single bit error or report a

noncorrectable event) or is allowed to complete (for error-free transfers) in a critical timing arc that often sets the upper limit of the operating frequency of the microcontroller. With the e2eECC scheme, the checkbit decode and error syndrome logic is located in the requesting bus master with generally more degrees of implementation freedom; the error/no\_error state determination is removed from the system bus cycle termination logic, producing an improved timing arc and generally higher operating speeds.

Errors that occur within the system interconnect are typically manifested as an incorrect address, incorrect write data, or incorrect read data to be presented to the slave or back to the master. Errors occurring within the storage typically manifest themselves eventually in corrupted read data or checkbits being returned to a requester.

The following diagram provides an overview of the e2eECC implementation on this chip.

**Figure 23-1. e2eECC overview**

### NOTE

Due to the e2eECC implementation as it relates to the cores, treat ECC errors discovered during cache line fills as imprecise.

# Chapter 24

## RAM Controller (PRAMC)

### 24.1 Chip-specific PRAM information

This chip has two instances of the PRAM module.

#### 24.1.1 PRAM optional read wait states

The following table shows programming values for the BO\_DIS and FT\_DIS fields of the PRAM's PRCR1 register and the resulting access timing for a WRAP4 burst. For additional information, see [Optional read wait-state](#).

**Table 24-1. Read wait states for WRAP4 burst**

| BO_DIS | FT_DIS | WRAP4 timing |
|--------|--------|--------------|
| 0      | 0      | 1-1-1-1      |
| 0      | 1      | 2-1-1-1      |
| 1      | 0      | 1-1-1-1      |
| 1      | 1      | 2-2-2-2      |

#### 24.1.2 Reset effects on System RAM accesses

If any of the following types of reset event occurs during a read or write operation to System RAM, the completion of that access depends on the cycle at which the reset occurs. Data read from or written to System RAM before the reset event occurred is retained, but no other address locations are accessed or changed.

- External reset via RESET pin
- FCCU reset
- JTAG reset

- Software system reset
- Dual core reset

If the System RAM is cached, cache lines might retain indeterminate data that is not written to memory unless the region is set for writethrough mode.

### NOTE

Standby memory might contain the previous data values if a reset occurs while the cache is running in copyback mode.

For descriptions of reset types, see [Reset sources](#).

#### 24.1.2.1 Other reset types

The software external reset does not affect internal logic and therefore does not cause RAM corruption for any RAMs.

For all other reset types, no System RAM retention is guaranteed.

#### 24.1.2.2 Other RAMs

For all other RAMs on the chip, no retention is guaranteed for any reset type.

### 24.2 Introduction

This section provides an overview of the Platform RAM Controller. The RAM controller acts as an interface between the system bus (AHB-Lite 2.v6) and the integrated system RAM. It converts the protocols between the system bus and the dedicated RAM array interface.

The RAM controller supports two 64-bit AHB interfaces and a 64-bit RAM array interface. The primary AHB port provides a connection to the platform crossbar for direct RAM access from the various crossbar masters. Shown below in [Figure 24-1](#) is a simplified block diagram depicting the position of the RAM controller within a typical platform architecture.

**Figure 24-1. Simplified platform block diagram**

The following list summarizes the key features of the RAM controller:

- System bus supports 64-bit data + 8-bit ECC AHB interfaces
- Array interface supports a 64-bit data + 8-bit ECC interface
- Late-write support via 64-bit data + 8-bit ECC storage buffer to support single-cycle write accesses
- Configurable read access timing (zero or one wait-state programmable) allowing use in large range of frequency targets
- Read-modify-write operation to support array write size less than a doubleword

The address path of the RAM controller contains a mux that chooses among the addresses presented on the system bus for a read request, either the address from the temporary holding register or the address from the late-write buffer. The temporary holding register contains the address which was presented during the AHB address phase of the write request. The request is stalled from being presented to the RAM by one cycle in order to present simultaneously the address and associated write data, which is not valid until the AHB dataphase. The late-write buffer holds write requests which are delayed to facilitate single-cycle response on the system bus.

The read datapath contains a mux that chooses the source of the read data to be presented on the system bus on a read request. In the event that a read request matches the contents of the late-write buffer, a RAM access is not required and the late-write buffer contents are selected onto the read databus. Otherwise, the read data is a result of a RAM access. Along with the read and write data, the corresponding ECC codewords traverse the entire datapath of the RAM controller, including the late-write storage buffer, to support end-to-end ECC (e2eECC) coverage.

The write datapath contains the mux that chooses the source of the write data as well as the control logic for generating read-modify-write operations on writes that are less than 64 bits in size. A write operation can be performed to empty the contents of the late-write buffer. In the case of back-to-back writes, the write may be forced to bypass the late-write buffer and instead be stored directly, precisely in the RAM.

### 24.3 SRAM controller memory map and register definition

The RAM controller module provides an IPS programming model mapped to a standard on-platform peripheral slot. The programming model can only be referenced using a 32-bit (word) access. Attempted references using different access sizes or to undefined (reserved) addresses generate an IPS error termination.

**NOTE**

Attempted updates to the PRAMC programming model while a PRAMC operation is in progress will result in non-deterministic behavior. Software must be architected to avoid this scenario by ensuring that PRAMC configuration changes are made only during system boot or when only one master is enabled. In multi-core devices, update the PRAMC configuration only when one core is active and no other masters, e.g., DMA or communications modules, are enabled. Move any instruction execution or memory references outside the system RAM while updating the PRAMC configuration, e.g., to the core local memory space.

**PRAMC memory map**

#### 24.3.1 Platform RAM Configuration Register 1 (PRAMC\_PRCR1)

The Platform RAM Configuration Register 1 (PRCR1) is used to specify operation of the RAM controller.

**NOTE**

This register is accessible only in supervisor mode. Accesses in user mode return a transfer error.

Address: 0h base + 0h offset = 0h

## 24.4 Functional description

This section describes the functions of the RAM controller.

### 24.4.1 Read and Write operations

The RAM controller processes read and write requests to on-chip RAM and provides a register interface for access to performance tuning functions.

#### NOTE

The RAM controller register interface is accessible only in supervisor mode. Accesses in user mode return a transfer error.

#### 24.4.1.1 Reads

Read transfers, of any size, can be configured to complete with a zero or one additional wait state response on the system bus.

#### 24.4.1.2 Optional read wait-state

The RAM controller can be optionally programmed to register RAM read data prior to returning it on the system bus. Setting the `PRCRx[FT_DIS]` field inserts a register in the read data path for use when operating the controller at high frequencies. The state of `PRCRx[FT_DIS]` field has no effect on writes.

A random, initial access will take 2 clock cycles (2T) to complete if `PRCRx[FT_DIS]=0`, and a WRAP4 burst will have an access time of 2-2-2-2. A random, initial access will take 3 clock cycles (3T) to complete if `PRCRx[FT_DIS]=1`, and a WRAP4 burst will have an access time of 3-2-2-2.

#### NOTE

The number of cycles taken for a RAM access can vary  $\pm 1$  clock cycle depending on the RAM speed relative to the PRAMC controller clock frequency. If system RAM is running at the same frequency as the PRAMC controller, a random initial access takes 2 clock cycles. If system RAM is running at a slower frequency, a random initial access may take 3 clock cycles. Subsequent burst beats take either 1 or 2 cycles

depending on RAM speed relative to the PRAMC controller clock frequency.

## 24.4.2 Writes

This section discusses various write operations of the RAM controller.

### 24.4.2.1 64-bit writes

Aligned 64-bit writes execute in a single AHB data phase cycle, allowing for zero wait states on back-to-back writes of these sizes. If, during the data phase of a write, a read is requested on the AHB, the write is registered in the late-write buffer, allowing the read to take place without a wait state. The valid buffered or late-write data is stored on the next available array address phase.

Back to back 64-bit writes execute slightly differently whereby the first write bypasses the late-write buffer. Rather, the write data is stored directly to the array in the same cycle in which it is valid on the AHB.

### 24.4.2.2 Less than 64-bit writes

Writes of size less than 64 bits incur a read-modify-write action as a consequence of the ECC coding scheme's 64-bit granularity. In the case of a read-modify-write action, the RAM controller performs SEC/DED on the read data. The write data is merged into the appropriate byte lanes along with the potentially corrected read data. A new codeword is generated based on the newly formed doubleword. The newly formed doubleword and its associated checkbits are subsequently written to the RAM. [Figure 24-3](#) provides details on the read-modify-write datapath. For details on the ECC coding scheme, refer to [Reliability considerations](#).

**Figure 24-3. Read-modify-write datapath**

On a read-modify-write operation, the array read data is registered after it is decoded and before it is merged with the AHB write data. Therefore, writes of size less than 64 bits require the insertion of one wait state before the data phase can be completed.

### 24.4.2.3 Unaligned writes

The RAM controller is compliant with the AMBA-AHB2.v6 Extensions specification with regard to byte strobes. The size of the transfer is sufficient to cover all bytes being written and covers more bytes in the case of an unaligned transfer. The address of the transfer is rounded down to the nearest boundary of the size of the transaction.

#### NOTE

Unaligned writes always generate read-modify-write operations in the RAM controller in order to preserve the validity of the ECC codeword.

## 24.5 Initialization/application information

It is essential that each memory address be written to a known value before it is read, to initialize the ECC. This includes reads generated from the read-modify-write operation which occurs when a write transfer of less than 64 bits or an unaligned write is requested. Without writing an address to a known value first, a read from this address will most likely generate an uncorrectable ECC event.

One possibility for initializing PRAMC memory space is to use a stored 64-bit word instruction such as Store Multiple Word (`e_stmw`) in Power Architecture VLE.

## 24.6 Reliability considerations

This section discusses reliability considerations of the RAM controller.

### 24.6.1 Hsiao ECC algorithm

The e2eECC scheme implements a single-error correction, double-error detection (SECDED) code using the so-called Hsiao odd-weight column criteria. These codes are named for M.Y. Hsiao, an IBM researcher who published extensively in the early 1970s on SECDED codes better suited for implementation in protecting (mainframe) computer memories than traditional Hamming codes.

The Hsiao codes are Hamming distance 4 implementations which provide the SECDED capabilities. The minimum odd-weight constraints defined by Hsiao are relatively simple in the resulting implementation of the parity check H matrix which defines the association between the data (and address) bits and the checkbits. They are:

1. There are no all-zeroes columns.
2. Every column is distinct.
3. Every column contains an odd number of ones, and hence is "odd weight".

In defining the H-matrix for this family of devices, these requirements from Hsiao were applied. Additionally, there are a variety of ECC codeword requirements associated with specific functional requirements associated with the system RAM that further dictated the specific column definitions. In any case, the resulting ECC is organized based on 64 data bits plus 29 address bits (the upper bits of the 32-bit address field minus the 3 bits which select the byte within the 64-bit (8-byte) data field).

| Checkbits [7:0] |    |    |    |    |    |    |    | Checkbits [7:0] |    |    |    |    |    |    |    | Checkbits [7:0] |    |    |    |    |    |    |    | Data Bit <sup>1</sup> |    |    |    |    |    |    |    |

- NXP Semiconductors

2. Bit numbering is AHB convention: bit 0 is LSB. D[7:0] corresponds to byte at address 0. D[63:56] corresponds to byte at address 7.

### 24.6.1.1 e2eECC considerations on less-than-64-bit write transactions

Recall writes of size less than 64-bit incur a read-modify-write action as a consequence of the ECC coding scheme 64-bit granularity. In the case of a read-modify-write action, the RAM controller performs SEC/DED on the read data. The RAM controller uses the following checkbit manipulation technique to ensure any faults in the PRAMC control logic associated with performing the read-modify-write action will ultimately be detectable by e2eECC:

- On an 8-, 16-, or 32-bit write request, the write data is presented by the master on the AHB bus in the correct byte lanes, with the non-pertinent byte lanes zeroed out, and the associated checkbit is based on this "zero-padded" write data.

Consider the following example whereby the master presents a 16-bit write request at address 0x40000000:

- The RAM controller detects that the request is a less-than-64-bit write request and initiates a read to address 0x40000000. An ECC check and potential single-bit correction is performed on the data returned from the RAM.

If a non-correctable ECC event is detected, the AHB request is terminated with error on the system bus.

- The RAM controller isolates the pertinent byte lanes of the read data by zero-padding the non-pertinent byte lanes and calculating the checkbit contribution associated with the read data in the byte lanes to be updated as a result of the write request.

- Merge the non-pertinent read data bytes with the write data in the appropriate byte lanes. Take the checkbit value that was stored in the RAM and remove the checkbit contribution associated with the read data in the byte lanes to be updated. Then introduce the checkbits associated with the write data. The result is ultimately a checkbit value associated with the complete 64-bit data to be written to the array.

This technique calculates the ultimate checkbit value on a read-modify-write transaction through a series of data manipulations, taking care to avoid discarding the original checkbits provided by the requesting master, such that faults in the crossbar (XBAR) and RAM controller datapath and control logic are covered by e2eECC.

Malfunction of the ECC logic described above may result in the corruption of the SEC/DED event reporting. The RAM controller performs EDC after ECC check on all read-modify-write transactions. If a mismatch is detected, indicating a failure in the ECC logic, the event is reported to the FCCU module.

24.6.2 Transaction monitor

The integrity of the address and data on a system RAM transaction is covered by e2eECC check performed by the requesting master. Fault detection coverage of the address path and control within the RAM controller is handled by a transaction monitor which verifies the integrity of the transactions between the RAM controller and the RAM array. The transaction monitor verifies RAM transactions initiated to service the following types of transactions:

- Direct system bus read or write request
- Read followed by write to fulfill a read-modify write transaction
- Write transaction to empty the late-write buffer

The function of the transaction monitor relies on a feedback path between the RAM controller and RAM array, wherein the RAM provides latched address and control feedback outputs as an indication of received inputs when a RAM access is initiated.

This feedback information is used by the RAM controller transaction monitor to verify the expected transaction. If a mismatch is detected, indicating a failure in the address generation or control logic within the RAM controller or the transmission path between the RAM controller and RAM array, the event is forwarded to the Fault Collection and Control Unit (FCCU).

Since writes to the RAM can be buffered, the transaction monitor also tracks the contents of the late-write buffer. When the late-write buffer is emptied, outputs from the RAM are evaluated against the expected contents of the late-write buffer as tracked by the transaction monitor.

As a countermeasure against false misses to the late-write buffer on reads, the transaction monitor also verifies the expected source of data returned on a read as supplied either from the RAM or from the late-write buffer.

## Chapter 25

# Flash Memory Controller (PFLASH)

### 25.1 Chip-specific PFLASH information

The PFLASH registers PFCR1, PFCR2, and PFAPR control the interaction of master modules with the flash memory array by enabling/disabling prefetch or by controlling access to the array on a per-master basis.

Fields in these registers refer to the masters' logical ID numbers. For example, the PFAPR[M2AP] field controls flash memory array access by logical master 2, and the PFAPR[M3AP] field controls flash memory array access by logical master 3.

- For the list of bus masters' logical IDs, see [XBAR master and slave assignments](#).
- For logical master ID numbers that are unused on this chip, the corresponding PFLASH register fields are reserved.

For more information about configuring the PFLASH, see the [Platform Flash Configuration Register 3 \(PFLASH\\_PFCR3\)](#) details.

### 25.2 Introduction

The flash memory controller has these functions:

- It acts as an interface between the system bus (AHB-Lite 2.v6) and the flash memory array.

The flash memory controller supports two 64-bit AHB buses and a 256-bit read data interface from each flash memory array. Each AHB port contains a 4-entry, 4-way set-associative mini-cache as well as an associated controller that prefetches sequential lines of data from the flash arrays into the mini-cache. This buffer mechanism serves to deliver flash read data with zero-wait state response on lines that reside in the cache. AHB requests that miss the cache generate the needed flash array access and are forwarded to

the AHB upon completion. Each mini-cache entry is 256 bits in size, matching the flash array page size and providing 512 bytes of total buffered storage. Along with the read and write data, the corresponding ECC codewords traverse the entire datapath of the flash memory controller, including the mini-cache, to support end-to-end ECC (e2eECC) coverage.

## 25.3 Features

The following list summarizes the key features of the flash memory controller:

- Two 64-bit AHB interface ports (p0, p1) allowing simultaneous access to dedicated prefetch mini-cache per slave port.
- 256-bit read data bus + 64-bit write data bus
- Configurable read buffering and line prefetching support via 4-entry, 4-way set-associative mini-cache plus prefetch controller per AHB port to provide single-cycle "buffer hit" read response.
- Configurable access control based on read/write and AHB master ID attributes.
- Configurable access timing (wait-state programmable) allowing use in a wide range of frequency targets.
- Optional address pipelining capability to maximize throughput.
- Support for reporting of single- and multi-bit flash ECC events on a 64-bit doubleword boundary.

## 25.4 Block diagrams

[Figure 25-1](#) illustrates the connections of the flash memory controller and flash memory array within the chip.

**Figure 25-1. Platform-centric simple block diagram with flash memory controller**

## 25.5 Flash memory controller memory map

The flash memory controller module provides an IPS programming model mapped to a standard 16 KB on-platform peripheral slot. The programming model consists of flash memory access configuration.

The programming model can only be referenced using a 32-bit (word) access. Attempted references using different access sizes or to undefined (reserved) addresses or in user mode generates an IPS error termination. The flash controller allows access to the programming model by all system bus masters.

The programming model can only be accessed in supervisor mode.

A write to any flash memory controller register, when executed concurrently with a flash memory access, will result in non-deterministic behavior and may include lockup of the flash memory controller. There is no idle indicator for the flash controller, so software must be architected to prevent any possible conflicts. The following recommendations will help.

- For multi-core devices, start only one core and execute initialization code to completion before starting the remaining cores.

- If flash must be reconfigured during application code execution, temporarily move all required code and data to system RAM before any writes to flash memory controller registers.
- If application software functionality includes invalidating a port read buffer, the recommended method for invalidating a port read buffer is:
  - a. Unlock the buffer's enable field by setting the PFLASH\_PFCR3[BFEN\_LK] field to '0'
  - b. Disable the buffer by setting it's associated enable field (PFLASH\_PFCR1[Pn\_BFEN]) to '0'
  - c. If needed, enable the buffer by setting it's associated enable field (PFLASH\_PFCR1[Pn\_BFEN]) to '1'

The above method requires updating flash memory controller registers, so software must ensure that no flash accesses are issued concurrently with any of the steps. In cases where that cannot be guaranteed, there is a workaround but its use is not generally recommended because it relies on a hardware side effect instead of the flash memory controller's built-in functions intended for invalidating port read buffers. The workaround is to issue an interlock write without an accompanying program or erase operation—an interlock write, without an accompanying program or erase, does not change any flash content.

### NOTE

1. If this workaround is implemented in application code, note that an interlock write invalidates only the buffers associated with the system bus port on which the interlock write was issued.
2. See the flash memory chapter for the steps to issue an interlock write.
3. See the flash memory controller's chip-specific information for any restrictions on the interlock write data size.

### 25.5.1 Platform Flash Configuration Register 1 (PFLASH\_PFCR1)

The PFlash Configuration Register 1 (PFCR1) controls the operation of Port p0 of the PFLASH\_C55FM flash memory controller.

#### NOTE

See the chip-specific platform flash controller information for information on the masters.

| 28<br>Reserved    | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| 29–30<br>P0_PFLIM | Port0 PFlash Prefetch Limit. This field controls the prefetch algorithm used by the prefetch controller. This field defines a limit on the maximum number of sequential prefetches which will be attempted between buffer misses. In all situations when enabled, only a single prefetch is initiated on each buffer miss or hit.<br><br>00 No prefetching or buffering is performed.<br>01 The referenced line is prefetched on a buffer miss, that is, prefetch on miss.<br>10 The referenced line is prefetched on a buffer miss, or the next sequential line is prefetched on a buffer hit (if not already present), that is, prefetch on miss or hit.<br>11 The referenced line is prefetched on a buffer miss, or the next sequential line is prefetched on a buffer hit (if not already present), that is, prefetch on miss or hit. |
| 31<br>P0_BFEN     | Port0 PFlash Line Read Buffers Enable. This bit enables or disables line read buffer hits. It is also used to invalidate the buffers. This bit can only be updated while PFCR3[BFEN_LK]=0.<br><br>0 The line read buffers are disabled from satisfying read requests, and all buffer valid bits are cleared.<br>1 The line read buffers are enabled to satisfy read requests on hits. Buffer valid bits may be set when the buffers are successfully filled.                                                                                                                                                                                                                                                                                                                                                                               |

**25.5.2 Platform Flash Configuration Register 2 (PFLASH\_PFCR2)**

The PFlash Configuration Register 2 (PFCR2) controls the operation of Port1 of the PFLASH\_C55FM flash memory controller.

**NOTE**

See the chip-specific platform flash controller information for details about the masters.

Address: 0h base + 4h offset = 4h

| 29–30<br>P1_PFLIM | Port1 PFlash Prefetch Limit. This field controls the prefetch algorithm used by the prefetch controller. This field defines a limit on the maximum number of sequential prefetches which will be attempted between buffer misses. In all situations when enabled, only a single prefetch is initiated on each buffer miss or hit. |

| 0–1<br>P0_WCFG | Port0 Way Configuration. This field controls the configuration of the line buffers for a given set across all four ways in the controller cache. The indexed set can be organized as a "pool" of available resources, or with a fixed partition between instruction and data buffers.<br><br>In all cases, when a buffer miss occurs, the flash page is assigned a location within the controller cache. Within the indexed set, the way is selected using a least-recently-used replacement policy, and the entry is then marked as most-recently-used for that set. If the flash access is for the next-sequential line (prefetch), the buffer is not marked as most-recently-used until the given address produces a buffer hit.<br><br>This field is initialized by hardware reset.<br><br>00 All four buffers in an indexed set are available for any flash access, that is, there is no partitioning of the buffers based on the access type.<br>01 Reserved |

|                   | <p>10 The buffers in an indexed set are partitioned into two groups with way 0 and 1 allocated for instruction fetches and way 2 and 3 for data accesses.</p> <p>11 The buffers are partitioned into two groups with way 0, 1, 2 allocated for instruction fetches and way 3 for data accesses.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| 2–3<br>P1_WCFG    | <p>Port1 Way Configuration. This field controls the configuration of the line buffers for a given set across all four ways in the controller cache. The indexed set can be organized as a "pool" of available resources, or with a fixed partition between instruction and data buffers.</p> <p>In all cases, when a buffer miss occurs, the flash page is assigned a location within the controller cache. Within the indexed set, the way is selected using a least-recently-used replacement policy, and the entry is then marked as most-recently-used for that set. If the flash access is for the next-sequential line (prefetch), the buffer is not marked as most-recently-used until the given address produces a buffer hit.</p> <p>This field is initialized by hardware reset.</p> <p>00 All four buffers are available for any flash access, that is, there is no partitioning of the buffers based on the access type.</p> <p>01 Reserved</p> <p>10 The buffers are partitioned into two groups with ways 0 and 1 allocated for instruction fetches and ways 2 and 3 for data accesses.</p> <p>11 The buffers are partitioned into two groups with buffers 0,1,2 allocated for instruction fetches and buffer 3 for data accesses.</p> |

| Field          | Description                                                                                                                                                                                                                                                                                                                                                                                                                           |
|----------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31<br>DERR_SUP | Data Error Suppression. Refer to the Embedded Flash Memory configuration information for which Flash blocks are affected by this field.<br><br>0 ECC events on data flash accesses are reported.<br>1 ECC events on data flash accesses are suppressed. Single-bit and multi-bit ECC errors are not reported. On multibit ECC events, the corrupted read data is replaced with a fixed, ECC-clean illegal opcode value of 0x15551555. |

**25.5.4 Platform Flash Access Protection Register (PFLASH\_PFAPR)**

The PFlash Access Protection Register (PFAPR) is used to control read and write accesses to the flash array.

**NOTE**

See the chip-specific platform flash controller information for details about the actual masters available on the device.

## 25.6 Functional description

The flash memory controller interfaces between:

- The AHB system bus ports
- Flash memory array

For accesses targeting the flash array, the flash memory controller generates read and write enables, block selects, array address, write size and write data as inputs to the flash array. The flash memory controller captures read data from the flash array and drives it onto the AHB system bus. Up to four pages of data (256-bit page size) may be buffered in each of four ways of the flash memory controller mini-cache. Lines may be prefetched in advance of being requested, allowing single-cycle (zero AHB wait-states) read data responses on buffer hits.

Several prefetch control algorithms are available for controlling line read buffer fills. Prefetch triggering may be restricted to instruction accesses only, data accesses only, or may be unrestricted. Prefetch triggering may also be controlled on a per-master basis.

Buffers may also be selectively enabled or disabled for allocation by instruction and data prefetch.

Access protections may be applied on a per-master basis for both reads and writes to support security and privilege mechanisms.

### 25.6.1 Basic interface protocol

Read accesses are terminated under control of the appropriate wait state settings. Thus, the access time of the operation is determined by the setting of the PFCR1[RWSC] field. Access timing can be varied to account for the operating conditions of the SoC (frequency, voltage, temp) by appropriately setting the PFCR1[RWSC] field.

### 25.6.2 Access protections

On-chip Flash memory accesses are subject to restrictions based on chip security implementation and/or requirements based on functional restrictions of the flash memory, e.g., a read access to a flash block while it is currently being written is not allowed. When a prohibited access is attempted, a system bus error termination results.

The flash memory controller may invoke a system bus error termination in the following scenarios:

- Attempted access by an AHB master whose corresponding read access control or write access control settings do not allow the access, thus causing a protection violation. See [Platform Flash Access Protection Register \(PFLASH\\_PFAPR\)](#) for more detail. In this case the flash memory controller does not initiate the requested flash array access.
- The flash returns an error response on an attempted access to a partition that is unavailable. (see [Embedded Flash Memory](#)).
- Attempted access by an AHB master to a reserved region in the flash memory map.

The flash array may also signal an error response to terminate a requested access due to improper sequencing during program/erase operations, improper sequencing during array integrity testing. When an error response is received the flash memory controller does not update or validate a page read buffer. An error response may be signaled on a read or interlock write operation. For more information on the specifics related to signaling of flash errors, including flash ECC events, array integrity testing and read-while-write events, refer to the flash memory chapter.

### 25.6.2.1 PFAPR - Platform Flash Access Protection Register (PFAPR)

The flash memory controller provides programmable, configurable access protections for both read and write cycles on a per-master basis via the PFlash Access Protection Register (PFAPR). It allows restriction of read and write requests on a per-master basis. This functionality is described in [Platform Flash Access Protection Register \(PFLASH\\_PFAPR\)](#). Detection of a protection violation results in an error response from the flash memory controller on the AHB transfer.

### 25.6.3 Access pipelining

Accesses to the flash array may be pipelined by driving a subsequent access address and control signals while waiting for the current access to complete. Pipelined access requests are always run to completion and are not aborted by the flash memory controller. Flash access pipelining allows for improved performance by reducing the access latency seen by the AHB master. Access pipelining may be applied only to read cycles targeting the flash array. Address pipelining is enabled by setting the PFCR1[APC] field.

Access pipelining is only supported for normal flash access .

#### NOTE

Not all combinations of PFCR1[APC] (Address Pipeline Control) and PFCR1[RWSC] (Read Wait State Control)

settings are recommended or supported. Please refer to the device data sheet for guidance.

## 25.6.4 Line read buffers and prefetch operation

The AHB ports of the flash memory controller each contain a four-way set-associative mini cache, where each way contains four page buffers which are used to hold data read from the flash arrays. Each 256-bit buffer operates independently, and is filled using a single array access. The buffers are used for both prefetch and normal demand fetches.

Prefetch triggering is controllable on a per-master and access-type basis (see [Platform Flash Configuration Register 1 \(PFLASH\\_PFCR1\)](#)). Bus masters may be enabled or disabled from triggering prefetches, and triggering may be further restricted based on whether a read access is for instruction or data. A read access by the flash memory controller may trigger a prefetch to the next sequential line of array data on the cycle following the request. The access address is incremented by 32-bytes, and a subsequent flash access is initiated. A flash array prefetch is initiated if the data is not already resident in a line read buffer. Prefetched data is always loaded into the least-recently-used buffer.

**Figure 25-6. Flash memory controller 4-entry, 4-way mini-cache organization**

Once the candidate line buffer has been selected, the flash array is accessed and read data loaded into the buffer. If the buffer load was in response to a miss, the buffer which was loaded is immediately marked as most-recently-used. If the buffer load was in response to a speculative fetch to the next-sequential line address after a buffer hit, *the recently-used status is not changed*. Rather, it is marked as most-recently-used only after a subsequent buffer hit.

This policy maximizes performance based on reference patterns of flash accesses and allows for prefetched data to remain valid when non-prefetch enabled bus masters are granted flash access.

Several algorithms are available for prefetch control which trade off performance for power. They are described in [Platform Flash Configuration Register 1 \(PFLASH\\_PFCR1\)](#). More aggressive prefetching may increase power due to the number of potentially discarded prefetches, but may increase performance by lowering average read latency.

For prefetching to occur, all of the following must apply:

1. PFCR{1,2}[P{0,1}\_BFEN] must be set to '1',
2. PFCR{1,2}[P{0,1}\_PFLIM] must be non-zero, and
3. Either PFCR{1,2}[P{0,1}\_IPFEN] or PFCR{1,2}[P{0,1}\_DPFEN] must be asserted.

Refer to [Platform Flash Configuration Register 1 \(PFLASH\\_PFCR1\)](#) for a description of these controls.

### 25.6.5 Instruction/Data prefetch triggering

Port0 prefetch triggering may be enabled for instruction reads via the PFCR1[IPFEN] control field, while Port0 prefetching for data reads is enabled via the PFCR1[DPFEN] control field. Additionally, the PFCR1[PFLIM] must also be set to enable prefetching on Port0. Refer to [Platform Flash Configuration Register 1 \(PFLASH\\_PFCR1\)](#) for a description of these controls. Prefetches are never triggered by write cycles.

Port1 prefetch triggering may be enabled for instruction reads via the PFCR2[IPFEN] control field, while Port1 prefetching for data reads is enabled via the PFCR2[DPFEN] control field. Additionally, the PFCR2[PFLIM] must also be set to enable prefetching on Port1. Refer to [Platform Flash Configuration Register 2 \(PFLASH\\_PFCR2\)](#) for a description of these controls. Prefetches are never triggered by write cycles.

### 25.6.6 Per-Master prefetch triggering

Prefetch triggering may be controlled for individual bus masters. Refer to [Platform Flash Configuration Register 1 \(PFLASH\\_PFCR1\)](#) for a description of these controls.

### 25.6.7 Buffer allocation

Allocation of the line read buffers is controlled via the PFCR3 control register, specifically the line buffer configuration ({P0,P1}\_WCFG) field. Refer to [Platform Flash Configuration Register 3 \(PFLASH\\_PFCR3\)](#). The buffers can be organized as a "pool" of available resources (with all four ways within a given set) or with a fixed partition between ways allocated to instruction or data accesses. For the fixed partitions, two

configurations are supported. In one configuration, ways 0 and 1 are allocated for instruction fetches and ways 2 and 3 for data accesses. In the second configuration, ways 0, 1 and 2 are allocated for instruction fetches and way 3 reserved for data accesses.

## 25.6.8 Reliability considerations

This section summarizes mechanism to enhance the reliability of flash by correcting and detecting faults.

### 25.6.8.1 e2eECC End-to-End ECC

#### 25.6.8.1.1 e2eECC and flash accesses

There are multiple complications associated with the use of the standard e2eECC algorithm with flash memory. The basic issues involve: the default state of a flash block that is erased (all ones) and the fact that programming an erased flash involves changing the state of memory bit from a logical 1 to a logical 0. These factors require that the system level e2eECC must be modified on references to the flash memory in three ways.

First, the all-ones codeword, since it reflects the state of an erased flash location, is treated as a valid error free encoding; in particular, it is required that the checkbits associated with the all all-ones value and the all zeroes data value are required to be the same with a checkbit value of 0xFF. Second, since an erased flash block generates an all-ones data for all locations, the address field cannot be included in the ECC code used by the flash. The flash array implements special address re-encoding logic based on the decoded array address to protect against address faults. Third, there are additional ECC implications associated with the flash memory and its support for EEPROM emulation.

In summary, the basic operation of an NVM bit cell impacts the e2eECC algorithm used in the flash memory in multiple ways. The required ECC adjustments are handled by the platform flash controller before data is written to the flash array(s) or applied to read data accessed from the array(s). These adjustments are two-fold. Consider a flash write during a programming event:

1. Remove the address field from the ECC codeword by XOR'ing the address calculation of the H-matrix from the checkbits.
2. Invert the resulting 8-bit ECC checkbit vector. This step is required to support the all-ones erased state.

On a flash read operation, a similar but "reversed" set of steps are performed as the data is driven into the system bus interconnect:

1. Invert the 8-bit ECC checkbit vector read from the flash.
2. Factor the address field into the ECC checkbits by XOR'ing the address calculation of the H-matrix.

Consider the following flash ECC example. Let the flash block containing address 0x00345678 be erased. The following is the sequence of operations:

1. Read address 0x00345678. Flash array returns fl\_rdata = 0xFFFFFFFF\_FFFFFFFF, fl\_cdata = 0xFF. The flash memory controller calculates the addr\_chkbit = 0xC4 using the H-matrix; it inverts the fl\_cdata vector to 0x00 and factors in the addr\_chkbit = 0xC4 to produce the following valid e2eECC codeword:

addr = 0x00345678, rdata = 0xFFFFFFFF\_FFFFFFFF, rchkbit = 0xC4 ( $0x00 \wedge 0xC4$ )

2. Program address 0x00345678 with data = 0xBABEFACE\_DEADBEEF. The initiating bus master calculates the e2eECC codeword as:

addr = 0x00345678, wdata = 0xBABEFACE\_DEADBEEF, wchkbit = 0xE3

Before performing the interlock write to the flash array, the flash memory controller adjusts the chkbit value as fl\_wchkbit = 0xD8 ( $0xE3 \wedge 0xFF \wedge 0xC4$ ) by toggling the original write checkbits and then factoring in the addr\_ecc. Accordingly, the codeword stored in the flash array is:

fl\_data = 0xBABEFACE\_DEADBEEF, fl\_checkbit = 0xD8

3. Read address 0x00345678. The flash array returns the stored codeword, fl\_rdata = 0xBABEFACE\_DEADBEEF, fl\_rchkbit = 0xD8. The flash memory controller inverts the checkbit vector and factors in the address checkbits ( $0xD8 \wedge 0xFF \wedge 0xC4$ ) to produce:

addr = 0x00345678, rdata = 0xBABEFACE\_DEADBEEF, rchkbit = 0xE3

This read codeword matches the original e2eECC codeword generated by the write.

Malfunction of the ECC logic described above may result in the corruption of the SEC/DED event reporting. The flash memory controller performs EDC after ECC check on all flash transactions. If a mismatch is detected, indicating a failure in the ECC logic, the event is reported to the device fault collection module.

### 25.6.8.2 Flash address generation check

Fault detection coverage of the address and data are handled by ECC performed within the flash and e2eECC performed at the master. Fault detection coverage of the address path and control within the flash memory controller rely on a feedback path between the flash controller and flash. Recall on a requested access to flash, the flash memory controller must decode the system AHB bus signals to generate the corresponding flash interface signals to invoke a flash lookup. In addition to providing the requested read data, the flash also provides output sidebands reflecting the encoded address and block selects used to perform the actual row lookup.

This sideband information is used by the flash memory controller to verify the expected transaction. If a mismatch is detected, indicating a failure in the address generation or control logic within the flash memory controller or the transmission path between the flash memory controller and flash array, the event is forwarded to the device fault collection module and the corresponding buffer is invalidated.

### 25.6.9 ECC on data flash accesses

For single-bit correction events, the corrected data and checkbits are returned to the requesting master.

In the event of a non-correctable error detection, a fixed, illegal opcode value (1555\_1555h) is returned to the requesting master along with the associated ECC checkbits as determined by the requesting address.

When PFCR3[DERR\_SUP] is enabled, ECC errors on data flash blocks are suppressed from being reported.

- In the event of a single-bit correction, the corrected data and checkbits are returned to the requesting master, and the single-bit correction event is suppressed from being reported.
- In the event of a non-correctable error detection, a fixed, illegal opcode value (1555\_1555h) is returned to the requesting master along with the associated ECC checkbits as determined by the requesting address and the non-correctable error event is suppressed from being reported.

#### NOTE

EEPROM should be avoided for storage of executable code.

### 25.6.10 Array integrity considerations

During an array integrity sequence, the flash memory array ignores any incoming read requests. When a flash array integrity check is in progress, the flash memory controller terminates all flash access requests with an error. More specifically, it aborts the incoming flash access requests and terminates the system bus transfer with an error.

# Chapter 26

## Embedded Flash Memory (C55FMC)

### 26.1 Chip-specific C55FMC information

#### NOTE

In production devices of this chip, the one-time-programmable Test Mode Disable Seal is programmed—that is, UTest is sealed—at the factory. For more information about the seal, see [Test mode disable seal](#).

#### 26.1.1 C55FMC register reset values

The following table lists C55FMC register reset values that are specific to this chip. For the reset values of all other C55FMC registers, see [Memory map and register definition](#).

Table 26-1. C55FMC register reset values

| Register                                                             | Reset value                                 |
|----------------------------------------------------------------------|---------------------------------------------|
| <a href="#">Extended Module Configuration Register (C55FMC_MCRE)</a> | 1001_2020h                                  |
| <a href="#">Over-Program Protection 0 register (C55FMC_OPP0)</a>     | Dependent on customer settings <sup>1</sup> |
| <a href="#">Over-Program Protection 1 register (C55FMC_OPP1)</a>     |                                             |
| <a href="#">Over-Program Protection 2 register (C55FMC_OPP2)</a>     |                                             |
| <a href="#">Over-Program Protection 3 register (C55FMC_OPP3)</a>     |                                             |

1. The reset value of the C55FMC\_OPPn registers, for each flash memory block mapped to a bit within each register, reflects whether the block has been marked as One Time Programmable (OTP). The C55FMC\_OPPn registers have the same bit-to-block mapping as the C55FMC\_LOCKn registers. A value of 1 indicates a block has been marked as OTP. The reset values of the C55FMC\_OPPn are similar to the reset values of the TDM\_OTPENn registers in the Tamper Detection Module (TDM).

The only C55FMC register that configures the use of the CSE-exclusive blocks is the OPP1 register. The LOCK1 and SEL1 registers do not configure these blocks.

### 26.1.3 C55FMC\_LOCKn register bit mapping

### 26.1.3.1 C55FMC\_LOCK0 register bit mapping

[illegible]

### 26.1.3.2 C55FMC\_LOCK1 register bit mapping

The flash memory blocks mapped to the **Lock 1 register (C55FMC\_LOCK1)** bits are as follows.

## NOTE

This register cannot be used to manage the blocks mapped to the register's implemented bits because the CSE module has exclusive access to these blocks. The bits' value is 1 to reflect the corresponding blocks' locked state, and the bits cannot be written to change that state.

| Register                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |  |

### 26.1.5.2 C55FMC\_OPP1 register bit mapping

The flash memory blocks mapped to the [Over-Program Protection 1 register \(C55FMC\\_OPP1\)](#) bits are as follows.

#### NOTE

When the value of a bit in this register reflects that the corresponding flash block has over-program protection, the

Chip-specific C55FMC information

protection applies to the block even though the CSE module has exclusive access to the block.

|                         | 0        | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15            | 16 | 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28 | 29 | 30 | 31                                  |                                     |

#### 26.1.5.4 C55FMC\_OPP3 register bit mapping

The flash memory blocks mapped to the [Over-Program Protection 3 register \(C55FMC\\_OPP3\)](#) bits are as follows.

|                         | 0        | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 | 11 | 12 | 13 | 14 | 15             | 16 | 17 | 18 | 19 | 20 | 21 | 22 | 23 | 24 | 25 | 26 | 27 | 28 | 29 | 30 | 31 |
|-------------------------|----------|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|
| Register Field          | Reserved |   |   |   |   |   |   |   |   |   |    |    |    |    |    | A256KOPP[15:0] |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| Flash Memory Block Name |          |   |   |   |   |   |   |   |   |   |    |    |    |    |    |                |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |

## 26.2 Introduction

The primary function of the embedded flash memory is to serve as electrically programmable and erasable non-volatile memory (NVM) that may be used for instruction or data storage.

The following figure shows the top-level diagram and functional organization of the flash memory unit.

**Figure 26-1. c55fmc block diagram**

## 26.2.1 Overview

The embedded flash memory is addressable by word (32 bits) or double word (64 bits) for program operation, and page (256 bits) for read operation. Multiple word or double-word writes may be done to the flash memory to fill up the program page buffer (256 bits), enabling page programming (256 bits, requiring 4 double-word writes) and quad-page programming (1024 bits, requiring 16 double-word writes). Flash memory reads always return 256 bits, although read page buffering may be performed by the Bus Interface Unit (BIU).

For more details on the embedded flash memory architecture and features, see [Functional Description](#).

## 26.2.2 Features

The embedded flash memory includes these distinct features:

- Test information stored in a dedicated nonvolatile block (referred to as the UTest block)
- OTP space made available in the UTest block
- Read page size of 256 bits (8 words)
- ECC with single-bit correction, double-bit detection (all 1's valid)
- Quad Page programming (64-bit granularity)
- Software programmable block program/erase restriction control
- Erasing of selected block(s)
- Independent programming of the UTest NVM block
- Embedded hardware program and erase algorithms
- Support for reading while writing when the accesses are to different partitions
- Erase suspend, program suspend, and erase-suspended program
- UTest mode (user-accessible test modes) including Array Integrity and Margin Read
- Triple Voted Flops for flash functions requiring high reliability, e.g., internal trimming, redundancy, and mode control

## 26.2.3 Modes of operation

Following is a brief description of the embedded flash memory operating modes.

- *User mode* is the default operating mode of the embedded flash memory. In this mode, it is possible to read and write registers, read and interlock write the memory

array, program the memory array, and erase the memory array. In this mode program and erase operations are initiated by doing array and register writes, and are controlled by an internal state machine.

- *UTest mode* is a tiered test mode strategy in which a portion of the factory test modes are made available. This mode is protected but accessible.

## 26.3 UTest NVM block

The UTest NVM block may be enabled by the BIU. When the UTest NVM space is enabled, all operations are mapped to the UTest NVM block. User-mode programming of the UTest NVM block is enabled only when MCR[PEAS] is high. The UTest NVM block is an OTP block (assuming Test Mode Disable Seal is written) - thus erase is not allowed.

The UTest NVM block supports RWW, and is grouped with the blocks in partition 0.

The UTest NVM block may be locked against program by using the lock registers.

Programming of the UTest NVM space has restrictions that are similar to those of the main space in terms of how ECC is calculated. Only one program operation is allowed per 64-bit ECC segment.

The UTest NVM block contains specified data that is needed for embedded flash memory or SoC features.

## 26.4 Test mode disable seal

Also included in the UTest NVM block is a mechanism to disable factory entry into Test mode. Extreme care must be taken when using this feature, as blocks that are selected to be protected in this method will not be able to have possible failures analyzed by factory failure analysts. Once sealed, the UTest block becomes OTP (Erase Locked, and Over Program Protection enabled). The UTest Block also is not accessible in Test mode.

Protection of this sort prevents all high-voltage operations to the flash executed by the internal state-machine, as well as reads through this state machine, and reads through the Array Integrity state machine when using Test mode interfaces.

UTest operations Margin Read and Array Integrity are also protected by preventing MISR updates on blocks selected for protection, although reads will still be done and single bit corrections and double bit detections will be logged. Protection through other interfaces is protected by normal User mode protection mechanisms, and are device-specific.

The method to disable factory entry into Test mode is to first program the Test Mode Disable Seal location to be 0x2D3C\_4B5A. Once the next reset is asserted, Test mode will be disabled.

It is possible to create a password to enable factory entry into test mode. This can be programmed into the Test Mode Disable Override Passcode. The passcode may not be 0x0000\_0000, 0xFFFF\_FFFF, or 0x5555\_5555. These are all invalid passcodes and will not be accepted to override. If it is desired by the customer that override never be possible, one of the three invalid passcodes should be put into this location. Passcode may be entered to authenticate entry (if enabled) by doing a 32-bit register write to register address 0x90. The UTest NVM block is always protected even if the Test Mode Disable Seal password is written. UTest operations Margin Read and Array Integrity are always protected even if the Test Mode Disable Seal password is written.

Only blocks selected in the Test Mode Disable Block Select field(s) are controlled by the Test Mode Disable feature. Thus it is possible for customers to selectively pick blocks that have this type of protection, and will not be eligible for factory failure analysis. Bits programmed to 0 in the Test Mode Disable Block Select field(s) will designate blocks that are controlled by the Test Mode Disable feature. If either Test Mode Disable Block Select - 0 or Test Mode Disable Block Select - 1 have a 0 programmed, that block will be protected. In order to provide two opportunities to select blocks for the Test Mode Disable, two regions are available, Test Mode Disable Block Select - 0 and Test Mode Disable Block Select - 1. The bit of these two regions are logically ANDed, to define which blocks are effectively selected for the Test Mode Disable feature. The Block Select field is organized as follows, and aligns with how blocks are defined in the LOCK registers.

**Table 26-2. Test mode disable block select**

| Block              | Bits used to select blocks |
|--------------------|----------------------------|
| Low Block Disable  | Data[13:0]                 |
| Unused             | Data[15:14]                |
| Mid Block Disable  | Data[31:16]                |
| High Block Disable | Data[47:32]                |
| 256K Block Disable | Data[95:48]                |

## 26.5 Memory map and register definition

The embedded flash memory map consists of a flash memory array (which includes main array space and UTest NVM space) and a region of registers associated with the programming model that enable flash memory array operation and modification.

The address space consists of 16 KB, 32 KB, 64 KB, and 256 KB blocks.

**C55FMC memory map**

| Address offset (hex) | Register name                                        | Width (in bits) | Access | Reset value                 | Section/ page               |
|----------------------|------------------------------------------------------|-----------------|--------|-----------------------------|-----------------------------|

## 26.5.1 Module Configuration Register (C55FMC\_MCR)

### NOTE

1. A number of Module Configuration Register (MCR) bits are locked against write by other bits. These locks are discussed in relationship to each bit in this section. Simultaneously writing bits which lock each other out is also discussed in [Functional Description](#).
2. See [Functional Description](#) for information about simultaneous MCR writes, and priority levels.

Address: 0h base + 0h offset = 0h

|                  | <p>corrupted. Since this bit is a status flag, it must be cleared to a 0 by writing a 1 to the register location. A write of 0 has no effect.</p> <p>0 Reads are occurring without voltage issues</p> <p>1 A previous read may have been corrupted due to read voltage being out of range</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| 1<br>RRE         | <p>Read Reference Error</p> <p>RRE provides information on previous reads monitoring the read reference. If the read reference is detected to be out of range, this bit is set to indicate that previous reads requested may have been corrupted. Since this bit is a status flag, it must be cleared to a 0 by writing a 1 to the register location. A write of 0 has no effect.</p> <p>0 Reads are occurring without reference issues</p> <p>1 A previous read may have been corrupted due to read reference being out of range</p>                                                                                                                                                                                                                                                                                                                                                     |
| 2<br>AEE         | <p>Address Encode Error</p> <p>AEE provides information on previous reads monitoring the address encode feature. On every read request to the flash, the incoming address is compared to an encoded address (row, column, and block) coming back from the memory array using the read data sense amplifier timing. If these two values do not match (zero selected, multiple selected, wrong selected), or the timing is incorrect, an address encode error will be recorded. If an address encode mismatch is detected, this bit is set to indicate that previous reads requested may have been corrupted. Since this bit is a status flag, it must be cleared to a 0 by writing a 1 to the register location. A write of 0 has no effect.</p> <p>0 Reads are occurring without address encode mismatches</p> <p>1 A previous read may be corrupted based on address encode mismatch</p> |
| 3<br>EEE         | <p>ECC after ECC Error</p> <p>EEE provides information on previous reads monitoring the ECC after ECC feature. On every read request to the flash, ECC is recalculated serially, and if there is a mismatch between the ECC calculations (taking into account corrections or detections) a late error will be reported. If an ECC after ECC mismatch is detected, this bit is set to indicate that previous reads requested may have been corrupted. Since this bit is a status flag, it must be cleared to a 0 by writing a 1 to the register location. A write of 0 has no effect.</p> <p>0 Reads are occurring without ECC after ECC mismatches</p> <p>1 A previous read may be corrupted based on ECC calculation errors</p>                                                                                                                                                          |
| 4–15<br>Reserved | <p>This field is reserved.</p> <p>This read-only field is reserved and always has the value 0.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| 16<br>EER        | <p>ECC Event Error</p> <p>This bit provides information on previous reads. If a double bit detection occurred, the EER bit is set to a '1'. This bit must then be cleared, or a reset must occur before it returns to a 0 state. This bit may not be set by software. In the event of a single bit detection and correction, this bit is not set. If EER is not set, or remains 0, this indicates that all previous reads (from the last reset, or clearing of EER) are correct. Since this bit is an error flag, it must be cleared to a 0 by writing a 1 to the register location. A write of 0 has no effect.</p> <p>0 Reads are occurring normally.</p> <p>1 An ECC Error occurred during a previous read.</p>                                                                                                                                                                        |
| 17<br>RWE        | <p>Read-While-Write Event Error</p> <p>This bit provides information on previous read-while-write (RWW) reads. If an RWW error occurs, this bit is set to 1. The bit must then be cleared, or a reset must occur before it returns to a 0 state. This bit may not be written to a 1. If RWE is not set, or remains 0, this indicates that all previous RWW reads (from the last</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

|                | <p>reset, or clearing of RWE) are correct. Since this bit is an error flag, it must be cleared to a 0 by writing a 1 to the register location. A write of 0 has no effect.</p> <p>0 Reads are occurring normally.<br/>1 A read-while-write error occurred during a previous read.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 18<br>SBC      | <p>Single Bit Correction</p> <p>SBC provides information on previous reads, if the SBCE is set. If a single bit correction occurred, the SBC bit is set to a 1. This bit must then be cleared, or a reset must occur before this bit returns to a 0 state. If SBC is not set, or remains 0, this indicates that all previous reads (from the last reset, or clearing of SBC) did not require a correction. Since this bit is a status flag, it must be cleared to a 0 by writing a 1 to the register location. A write of 0 has no effect.</p> <p>0 Reads are occurring without corrections.<br/>1 A Single Bit Correction occurred during a previous read.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| 19<br>Reserved | <p>This field is reserved.<br/>This read-only field is reserved and always has the value 0.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                           |
| 20<br>PEAS     | <p>Program Access Space</p> <p>PEAS indicates which space is valid for program or erase operations — either main array space or UTest NVM space. It should be noted that if the flash is sealed, and the Test Mode Disable Seal is programmed, erase is not allowed on the UTest NVM space. PEAS = 0 indicates the main address space is active for all program or erase operations. PEAS = 1 indicates the UTest NVM address space is active for program or erase (if applicable) operations. The value in PEAS is captured and held when the UTest NVM block is enabled with the first interlock write done for program operations (and erase operations if the flash is unsealed). The value of PEAS is retained between sampling events (in other words, subsequent first interlock writes). The value in PEAS may be changed during erase-suspended program, and reverts back to its original state once the erase-suspended program is completed. PEAS is read only.</p> <p>0 UTest NVM address space is disabled for program/erase and main address space enabled.<br/>1 UTest NVM address space is enabled for program/erase and main address space disabled.</p> |
| 21<br>DONE     | <p>State Machine Status</p> <p>DONE indicates whether the embedded flash memory is performing a high voltage operation. DONE is set to a 1 on termination of the embedded flash memory reset. DONE is read only. DONE is set to a 1 at the end of program and erase high voltage sequences.</p> <p><b>NOTE:</b> This bit transitions from a 0 to 1 during reset and remains at 1 after reset.</p> <p>0 Flash memory is executing a high voltage operation.<br/>1 Flash memory is not executing a high voltage operation.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| 22<br>PEG      | <p>Program/Erase Good</p> <p>The PEG bit indicates the completion status of the last flash memory program or erase sequence for which high voltage operations were initiated. The value of PEG is updated automatically during the program and erase high voltage operations. Aborting a program/erase high voltage operation causes PEG to be cleared, indicating the sequence failed. PEG is set to a 1 when the embedded flash memory is reset. PEG is read only.</p> <p>The value of PEG is valid only when PGM = 1 or ERS = 1 and after DONE transitions from 0 to 1 due to an abort or the completion of a program/erase operation. PEG is valid until PGM/ERS makes a 1 to 0 transition or EHV makes a 0 to 1 transition. The value in PEG is not valid after a 0 to 1 transition of DONE caused by PSUS or ESUS being set to logic 1. If PGM and ERS are both 1 when DONE makes a qualifying 0 to 1 transition the value of PEG indicates the completion status of the PGM sequence. This happens in an erase-suspended program operation.</p>                                                                                                                    |

| Field             | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
|-------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                   | <p>PEG will be 0 if an Erase-Suspended Program is attempted to a block that has been selected for Erase.</p> <p>PEG will also be 0 in the event of an error in the interlock write for program only. An error in the interlock write occurs when the ECC value provided to the flash memory does not match the ECC calculated within the flash memory. In the event of this, high voltage will not be applied to the array, and PEG will indicate a failed program.</p> <p><b>NOTE:</b></p> <ol style="list-style-type: none"> <li>1. If program or erase operations are attempted on blocks that are locked, the response from embedded flash memory is PEG = 1, indicating that the operation was successful, and the contents of the block are properly protected from the program or erase operation. PEG = 1 is also true if an abort occurs during an HV request to a locked block.</li> <li>2. If a program operation is attempted to a location marked as OTP, the response from the embedded flash memory is PEG = 0, indicating that the operation was not allowed, and the value interlocked was not programmed, since the desired doubleword was already programmed with a previous program operation.</li> </ol> <p>0 Program or erase operation failed.<br/>1 Program or erase operation successful.</p> |
| 23<br>PECIE       | <p>Program/Erase Complete Interrupt Enable</p> <p>PECIE provides a mechanism to trigger an interrupt request upon the assertion of the DONE flag due to a high voltage event (program or erase) finishing (normal, abort, suspend). If PECIE is written while not in a high voltage event, the interrupt will not immediately trigger, but will trigger after the next high voltage event is completed.</p> <p>0 An interrupt request will not be generated when the DONE flag is set.<br/>1 An interrupt request will be generated when the DONE flag is set.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 24–26<br>Reserved | <p>This field is reserved.<br/>This read-only field is reserved and always has the value 0.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| 27<br>PGM         | <p>Program</p> <p>PGM is used to set up embedded flash memory for a program operation. A 0 to 1 transition of PGM initiates a program sequence. A 1 to 0 transition of PGM ends the program sequence. PGM can be set only under one of the following conditions:</p> <ul style="list-style-type: none"> <li>• User mode read (ERS is low and UTE is low)</li> <li>• Erase suspend (ERS and ESUS are 1) with EHV low</li> </ul> <p>PGM can be cleared only when PSUS and EHV are low and DONE is high. PGM is cleared on reset.</p> <p>0 Flash memory is not executing a program sequence.<br/>1 Flash memory is executing a program sequence.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |
| 28<br>PSUS        | <p>Program Suspend</p> <p>PSUS is used to indicate the embedded flash memory is in program suspend or in the process of entering a suspend state. The embedded flash memory is in program suspend when PSUS = 1 and DONE = 1. PSUS can be set high only when PGM and EHV are high. A 0 to 1 transition of PSUS starts the sequence which sets DONE and places the embedded flash memory in program suspend. The embedded flash memory enters suspend within Tpsus of this transition.</p> <p>PSUS can be cleared only when DONE and EHV are high. A 1 to 0 transition of PSUS with EHV = 1 starts the sequence which clears DONE and returns the embedded flash memory to program. The embedded flash memory cannot exit program suspend and clear DONE while EHV is low. PSUS is cleared on reset.</p> <p>0 Program sequence is not suspended.<br/>1 Program sequence is suspended.</p>                                                                                                                                                                                                                                                                                                                                                                                                                               |

| 29<br>ERS  | <p>Erase</p> <p>ERS is used to set up embedded flash memory for an erase operation. A 0 to 1 transition of ERS initiates an erase sequence. A 1 to 0 transition of ERS ends the erase sequence. ERS can only be set in user mode read (PGM is low and UTE is low). ERS can be cleared only when ESUS and EHV are low and DONE is high. ERS is cleared on reset.</p> <p>0 Flash memory is not executing an erase sequence.<br/>1 Flash memory is executing an erase sequence.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| 30<br>ESUS | <p>Erase Suspend</p> <p>ESUS is used to indicate that the embedded flash memory is in erase suspend or in the process of entering a suspend state. The embedded flash memory is in erase suspend when ESUS = 1 and DONE = 1. ESUS can be set high only when ERS and EHV are high and PGM is low. A 0 to 1 transition of ESUS starts the sequence which sets DONE and places the flash memory in erase suspend. The embedded flash memory enters suspend within T<sub>es</sub> of this transition.</p> <p>ESUS can be cleared only when DONE and EHV are high and PGM is low. A 1 to 0 transition of ESUS with EHV = 1 starts the sequence which clears DONE and returns the embedded flash memory to erase. The embedded flash memory cannot exit erase suspend and clear DONE while EHV is low. ESUS is cleared on reset.</p> <p>0 Erase sequence is not suspended.<br/>1 Erase sequence is suspended.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| 31<br>EHV  | <p>Enable High Voltage</p> <p>The EHV bit enables the embedded flash memory for a high voltage program/erase operation. EHV is cleared on reset. EHV must be set after an interlock write to start a program/erase sequence. EHV may be set, initiating a program/erase, after an interlock under one of the following conditions:</p> <ul style="list-style-type: none"> <li>• Erase (ERS = 1, ESUS = 0)</li> <li>• Program (ERS = 0, ESUS = 0, PGM = 1, PSUS = 0)</li> <li>• Erase-suspended program (ERS = 1, ESUS = 1, PGM = 1, PSUS = 0)</li> </ul> <p>If a program operation is to be initiated while an erase is suspended, EHV must be cleared while in erase suspend before setting PGM.</p> <p>In normal operation, a 1 to 0 transition of EHV with DONE high, PSUS low, and ESUS low terminates the current program/erase high-voltage operation. In an erase-suspended program operation, a 1 to 0 transition of EHV with DONE high, ESUS high, PGM high, ERS high, and PSUS low terminates the program that is the current high voltage operation.</p> <p>When an operation is aborted, there is a 1 to 0 transition of EHV with DONE low and the suspend bit for the current program/erase sequence low. An abort causes the value of PEG to be cleared, indicating a failed program/erase; address locations being operated on by the aborted operation contain indeterminate data after an abort. EHV may not be written to a 1 after an abort is requested (EHV being cleared) and before DONE transitions high.</p> <p>A suspended operation cannot be aborted. EHV may be written during suspend. EHV must be high for the embedded flash memory to exit suspend. EHV may not be written after a suspend bit is set high and before DONE transitions high. EHV may not be set low after the current suspend bit is set low and before DONE transitions low.</p> <p><b>NOTE:</b> Aborting a high voltage operation leaves FC addresses in an indeterminate data state. This may be recovered by executing an erase on the affected blocks.</p> <p>0 Flash memory is not enabled to perform a high voltage operation.<br/>1 Flash memory is enabled to perform a high voltage operation.</p> |

## 26.5.2 Extended Module Configuration Register (C55FMC\_MCRE)

### NOTE

The reset value of this register is set at the factory and varies among devices. See the chip-specific C55FMC information for details.

| 0<br>TSLOCK | <p>UTest NVM Lock.</p> <p>This bit is used to lock the UTest NVM block from programs (erase protection not needed since UTest NVM is OTP and not erasable). A value of 1 in the TSLOCK register signifies that the UTest NVM block is locked for program. A value of 0 in the TSLOCK register signifies that the UTest NVM block is available to receive program pulses.</p> <p>The TSLOCK register is not writable once an interlock write is completed until DONE is set at the completion of the requested operation. Likewise, TSLOCK register is not writable if a high voltage operation is suspended.</p> |

The reset value is always 1, and register writes have no effect.<br>0 Block is available for program and erase operations.<br>1 Block is locked and unavailable for program and erase operations |

## 26.5.4 Lock 1 register (C55FMC\_LOCK1)

The Lock 1 (LOCK1) register provides a means to protect blocks from being modified.

Address: 0h base + 14h offset = 14h

| 0–31<br>A256KSEL | <p>256 KB Block Select.</p> <p>A value of 1 in the select register signifies that the block is selected for erase. A value of 0 in the select register signifies that the block is not selected. The reset value for the select registers is 0, or unselected. The block numbering for the 256 KB blocks starts with 256KSEL[0] and continues until all blocks are accounted.</p> <p>The blocks must be selected (or unselected) before doing an erase interlock write as part of the erase sequence. The select register is not writable once an interlock write is completed until DONE is set at the completion of the requested operation, or if a high-voltage operation is suspended.</p> <p>256KSEL is also not writeable during UTest operations, when AIE is high.</p> <p>In the event that blocks are not present (due to configuration or total memory size), the corresponding select bits default to unselected, and are not writable. The reset value is always 0, and register writes have no effect.</p> <p>0 The block is not selected<br/>1 The block is selected for erase</p> |

## 26.5.10 Select 3 register (C55FMC\_SEL3)

The Select 3 (SEL3) register provides a means to select blocks to be operated on during erase.

Address: 0h base + 44h offset = 44h

## 26.5.11 Address register (C55FMC\_ADR)

The Address register (ADR) provides the first failing address in the event of a failure (ECC or PGM/Erase state machine), as well as single bit correction information.

Address: 0h base + 50h offset = 50h

| 8–28<br>ADDR      | Address. The ADR provides the first failing address in the event of ECC event error (EER set), Single Bit Correction (SBC set), as well as providing the address of a failure that may have occurred in a state machine operation (PEG cleared). ECC event errors take priority over Single Bit Corrections, which take priority over state machine errors. This is especially valuable in the event of an RWW operation, where the read senses an ECC error or Single Bit correction, and the state machine fails simultaneously. The failing address for ECC event error is held until EER is cleared. The failing address for Single Bit Correction is held until an ECC event error, or until SBC is cleared. State machine address is held until an ECC event error or Single Bit Correction event occurs, or until the next state machine event (PEG cleared) occurs. This address is always a doubleword address that selects 64 bits.<br><br>ADDR[23:3] is an offset from a base address of 0x0 for each block size region. The aH, aM, aL, a16k, a32k, a64k, and a256k qualify the block size region the ADDR field. |
| 29–31<br>Reserved | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |

26.5.12 UTest 0 register (C55FMC\_UT0)

The User Test 0 (UT0) register provides a means to control UTest. UTest mode gives the ability to perform test features on the flash memory. This register is only writable when the flash memory is put into UTest mode by writing a passcode.

Address: 0h base + 54h offset = 54h

C55FMC\_UT0 field descriptions

| Field     | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
|-----------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0<br>UTE  | <p>U-Test Enable. This status bit gives indication when U-Test is enabled. All bits in UT0, UM0, UM1, UM2, UM3, UM4, UM5, UM6, UM7, UM8 and UM9 are locked when this bit is 0. This bit is not writeable to a 1, but may be cleared. The reset value is 0. The method to set this bit is to provide a password, and if the password matches, the UTE bit is set to reflect the status of enabled, and is enabled until it is cleared by a register write. The UTE password will only be accepted if PGM = 0 and ERS = 0 (program and erase are not being requested). UTE can only be cleared if AID = 1, MRE and AIE = 0. While clearing UTE, writes to set AIE or MRE will be ignored. For UTE, the password 0xF9F9_9999 must be written to the UT0 register.</p> <p>0 All bits in the UT0, UM0, UM1, UM2, UM3, UM4, UM5, UM6, UM7, UM8 and UM9 registers are locked<br/>1 Bits in the UT0, UM0, UM1, UM2, UM3, UM4, UM5, UM6, UM7, UM8 and UM9 registers are unlocked</p> |
| 1<br>SBCE | <p>Single Bit Correction Enable. SBCE enables Single Bit Correction results to be observed in SBC. ECC corrections that occur when SBCE is cleared will not be logged.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

|                   | 0 Single Bit Corrections observation is disabled.<br>1 Single Bit Correction observation is enabled.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| 2–12<br>Reserved  | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| 13<br>CPR         | Customer Programmable Read Voltage and Reference Detection. This bit is used to control the error generation for the Customer Programmable Detection area in the UTest block. If this bit is set, and the Customer Programmable Detection location in UTest is read, a Read Voltage and Reference Error detection will be noted. This bit may not be set while CPE and CPA are set. If CPE or CPA are high, this bit will be locked. If attempts are made to write CPR, CPA or CPE simultaneously, none of them will be written.<br><br>0 Customer Programmable Read Voltage and Reference Detection Error is not enabled<br>1 Customer Programmable Read Voltage and Reference Detection Error is enabled |
| 14<br>CPA         | Customer Programmable Address Encode Detection. This bit is used to control the error generation for the Customer Programmable Detection area in the UTest block. If this bit is set, and the Customer Programmable Detection location in UTest is read, a Address Encode Error detection will be noted. This bit may not be set while CPE and CPR are set. If CPE or CPR are high, this bit will be locked. If attempts are made to write CPR, CPA or CPE simultaneously, none of them will be written.<br><br>0 Customer Programmable Address Encode Detection Error is not enabled<br>1 Customer Programmable Address Encode Detection Error is enabled                                                 |
| 15<br>CPE         | Customer Programmable EDC after ECC Detection. This bit is used to control the error generation for the Customer Programmable Detection area in the UTest block. If this bit is set, and the Customer Programmable Detection location in UTest is read, a EDC after ECC Error detection will be noted. This bit may not be set while CPR and CPA are set. If CPR or CPA are high, this bit will be locked. If attempts are made o write CPR, CPA or CPE simultaneously, none of them will be written.<br><br>0 Customer Programmable EDC after ECC Detection Error is not enabled<br>1 Customer Programmable EDC after ECC Detection Error is enabled                                                      |
| 16–21<br>Reserved | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| 22<br>NAIBP       | Next Array Integrity Break Point. If AIBPE is set, NAIBP will be set once a single bit correction (if enabled) or double bit detection is noted during the Array Integrity test. NAIBP is not writable to 1, but may be cleared to 0. Clearing NAIBP to 0, will enable the Array Integrity operation to be re-started after a breakpoint is encountered. If the Array Integrity operation completes without encountering another correction or detection, AID will be set with NAIBP remaining 0.<br><br>1 Array Integrity state machine is at a break point.<br>0 Array Integrity state machine is not currently at a break point.                                                                        |
| 23<br>AIBPE       | Array Integrity Break Point Enable. If you want to enable breakpoints during an array integrity test, AIBPE may be set. See NAIBP description for more information about array integrity breakpoints.<br><br>1 Array Integrity breakpoints are enabled during Array Integrity Checks.<br>0 Array Integrity breakpoints are not enabled.                                                                                                                                                                                                                                                                                                                                                                    |
| 24<br>Reserved    | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| 25<br>AISUS       | Array Integrity Suspend. AISUS enables a suspend of an Array Integrity Operation. Array Integrity may be suspend by Setting AISUS, and resumed by clearing AISUS. AISUS is writeable only when AID is low. AISUS is clearable only when AID is high. Attempting to write AISUS and AIE on the same clock cycle will result in only AIE getting written.                                                                                                                                                                                                                                                                                                                                                    |

| Field          | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
|----------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                | <p>1 Array integrity sequence is suspended.</p> <p>0 Array integrity sequence not suspended.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |
| 26<br>MRE      | <p>Margin Read Enable. MRE combined with MRV enables user margin reads to be done. Normal user reads are not affected by MRE, although user reads while the margin read operation is ongoing are not supported. MRE is not writable if AID is low, or if AISUS is high, or if NAIBP is high.</p> <p>1 Margin reads are enabled.</p> <p>0 Margin reads are not enabled.</p>                                                                                                                                                                                                                                                                                                  |
| 27<br>MRV      | <p>Margin Read Value. MRV selects the margin level that is being checked. Margin can be checked to an erased level (MRV=1) or to a programmed level (MRV=0). In order for this value to be valid, MRE must also be set. MRV is not writable if AID is low, or if AISUS is high, or if NAIBP is high.</p> <p>1 One's margin reads are requested.</p> <p>0 Zero's margin reads are requested.</p>                                                                                                                                                                                                                                                                             |
| 28<br>Reserved | <p>This field is reserved.</p> <p>This read-only field is reserved and always has the value 0.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
| 29<br>AIS      | <p>Array Integrity Sequence. AIS determines the address sequence to be used during array integrity checks. The default sequence (AIS = 0) is meant to replicate sequences that normal user code follows, and thoroughly checks the read propagation paths. This sequence is proprietary. The alternative sequence (AIS = 1) is logically sequential.</p> <p>It should be noted that the time to run a sequential sequence is shorter than the time to run the proprietary sequence. AIS is not writeable if AIE is high.</p> <p>1 Array integrity sequence is sequential.</p> <p>0 Array integrity sequence is proprietary sequence.</p>                                    |
| 30<br>AIE      | <p>Array Integrity Enable. AIE set to one starts the array integrity check done on all selected blocks. The address sequence is determined by AIS, and the MISR (UM0 through UM9) can be checked after the operation is complete, to determine if a correct signature has been obtained. Once an array integrity operation is requested (AIE=1), it may be terminated by clearing AIE if the operation has finished (AID = 1) or aborted by clearing AIE if the operation is ongoing (AID = 0). AIE is not simultaneously writable to a 1 as UTE is being cleared to a 0.</p> <p>0 Array integrity checks are not enabled.</p> <p>1 Array integrity checks are enabled.</p> |
| 31<br>AID      | <p>Array Integrity Done. AID is cleared upon an array integrity check being enabled (to signify the operation is ongoing). Once completed, AID is set to indicate that the array integrity check is complete. At this time the MISR (UMR registers) can be checked. AID may also assert if breakpoints are enabled (AIBPE is set), an abort is requested or a suspend is requested. AID cannot be written, and is status only.</p> <p>0 Array integrity check is ongoing.</p> <p>1 Array integrity check is done.</p>                                                                                                                                                       |

## 26.5.13 UMISR register (C55FMC\_UMn)

The Multiple Input Signature registers provide a means to evaluate array integrity.

Address: 0h base + 58h offset + (4d × i), where i=0d to 8d

### C55FMC\_UMn field descriptions

| Field        | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
|--------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–31<br>MISR | <p>MISR[31:0]. The MISR registers accumulate a signature from an array integrity event. The MISR captures all data fields, as well as ECC fields, and the ECC error signal. Data (read and ECC) captured in the MISR is after the ECC logic, and represents corrected data (if required).</p> <p>The MISR can be seeded to any value by writing the MISR registers.</p> <p><b>NOTE:</b> Writing the MISR register during an array integrity operation (including suspend or breakpoint) although possible, is not recommended. A write of the MISR registers at this point may alter the final signature in an unpredictable way.</p> <p>The MISR register provides a means to calculate a MISR during array integrity operations.</p> <p>The MISR can be represented by the following polynomial:</p> $x^{289} + x^7 + x^6 + x^5 + x^4 + x^2 + 1$ <p>The MISR is calculated by taking the previous MISR value and then "exclusive ORing" the new data. In addition the most significant bit (in this case it is MISR[288]), is then "exclusive ORed" into input of MISR[7], MISR[6], MISR[5], MISR[4], MISR[2] and MISR[0]. The result of the "exclusive OR" is shifted left on each read.</p> <p>The MISR register is used in array integrity operations.</p> <p>If during address sequencing, reads extend into an invalid address location (in other words, greater than the maximum address for a given array size) then reads are still executed to the array, but the results from the array read are not deterministic. In this instance, the MISR registers is not recalculated, and the previous value is retained.</p> |

## 26.5.14 UMISR register (C55FMC\_UM9)

The Multiple Input Signature registers provide a means to evaluate array integrity.

Address: 0h base + 7Ch offset = 7Ch

| 31<br>MISR       | <p>MISR[288].</p> <p>The MISR registers accumulate a signature from an array integrity event. The MISR captures all data fields, as well as ECC fields, and the ECC error signal. Data (read and ECC) captured in the MISR is after the ECC logic, and represents corrected data (if required).</p> <p>The MISR can be seeded to any value by writing the MISR registers.</p> <p><b>NOTE:</b> Writing the MISR register during an array integrity operation (including suspend or breakpoint) although possible, is not recommended. A write of the MISR registers at this point may alter the final signature in an unpredictable way.</p> <p>The MISR register provides a means to calculate a MISR during array integrity operations.</p> <p>The MISR can be represented by the following polynomial:</p> $x^{289} + x^7 + x^6 + x^5 + x^4 + x^2 + 1$ <p>The MISR is calculated by taking the previous MISR value and then "exclusive ORing" the new data. In addition the most significant bit (in this case it is MISR[288]), is then "exclusive ORed" into input of MISR[7], MISR[6], MISR[5], MISR[4], MISR[2] and MISR[0]. The result of the "exclusive OR" is shifted left on each read.</p> <p>The MISR register is used in array integrity operations.</p> <p>If during address sequencing, reads extend into an invalid address location (in other words, greater than the maximum address for a given array size) then reads are still executed to the array, but the results from the array read are not deterministic. In this instance, the MISR registers is not recalculated, and the previous value is retained</p> |

### 26.5.15 Over-Program Protection 0 register (C55FMC\_OPP0)

The Over-Program Protection 0 (OPP0) register provides a means to protect blocks from being over-programmed. This register shows the over-program protection status.

#### NOTE

The reset value of this register is set at the factory and varies among devices. See the chip-specific C55FMC information for details.

**26.5.16 Over-Program Protection 1 register (C55FMC\_OPP1)**

The Over-Program Protection 1 (OPP1) register provides a means to protect blocks from being over programmed. This register shows the over-program protection status.

**NOTE**

The reset value of this register is set at the factory and varies among devices. See the chip-specific C55FMC information for details.

## 26.5.19 Test Mode Disable Password Check register (C55FMC\_TMD)

The Test Mode Disable Password Check (TMD) register provides a means to provide a challenge password to disable the Test Mode Disable Seal block select.

Writes to the register have no effect except for a password challenge. Reads to this register always return 0.

## 26.6 Functional Description

The embedded flash memory consists of address spaces in four groupings:

- Low address space
- Mid address space
- High address space
- 256 KB address space

The main address space is divided into partitions. Each address space mentioned above consists of a partition pair. Partitions are used to determine locations for valid read-while-write (RWW) operations. While the embedded flash memory is performing a write (program or erase) to a given partition, it can simultaneously perform a read from any other partition. For program operations, only the address specified by an interlock write determines the partition being written (block locking and block select registers do not determine the RWW partitions being written). For erase operations, only blocks that are selected and unlocked determine the RWW partitions being written.

The main address space is also divided into blocks to implement independent erase and program protection. The UTest NVM block also exists as a block, and has independent program protection. The UTest NVM block is included to support systems that require nonvolatile memory (NVM) for security or to store system initialization information.

A number of MCR bits are protected against write when another bit, or set of bits, is in a specific state. These write locks are covered on a bit-by-bit basis in [Module Configuration Register \(C55FMC\\_MCR\)](#). The write locks do not consider the effects of trying to write two or more bits simultaneously. The embedded flash memory does not allow bits to be written simultaneously which put the device into an illegal state. This is implemented through a priority mechanism among the bits. The bit changing priorities are detailed in the following table.

**Table 26-32. MCR bit set/clear priority levels**

| Priority level | MCR Bit(s) |
|----------------|------------|
| 1              | ERS        |
| 2              | PGM        |
| 3              | EHV        |
| 4              | ESUS, PSUS |

If two or more MCR bits are written simultaneously only the bit with the lowest priority number is accepted for modification. Setting two bits with the same priority number is prevented by existing write locks or do not put the flash memory in an illegal state.

For example, setting ERS and PGM simultaneously results in only ERS being set. Attempting to clear EHV while setting PSUS results in EHV being cleared, while PSUS is unaffected.

Each read of the embedded flash memory retrieves a page, or eight consecutive words (256 bits), of information. The address for each word retrieved within a page differs from the other addresses in the page only by address bits [4:2]. The flash memory page read architecture easily supports both cache and burst mode at the BIU level for high-speed read applications.

The embedded flash memory supports fault tolerance through error correction code (ECC) and error detection. ECC implemented within the embedded flash memory corrects single-bit failures and detects double-bit failures.

A software mechanism is provided to independently lock and unlock each block.

Program and erase of the embedded flash memory requires multiple system clock cycles to complete. The program and erase sequence may be suspended or aborted.

The embedded flash memory may reside in various modes. The modes that are available include:

- User mode
- UTest mode

Each of these modes is discussed in detail in the following sections.

## **26.6.1 User Mode**

In user mode the embedded flash memory may be read and written (register writes and interlock writes), programmed or erased. The following sub-sections define all actions that may be performed in user mode.

### **26.6.1.1 Read and write**

The default state of the embedded flash memory is read. The main and UTest NVM address space can be read only in the read state. The MCR is always available for read. The embedded flash memory enters the read state on reset. The embedded flash memory is in the read state under four sets of conditions:

- The read state is active when the embedded flash memory is enabled (User Mode Read).
- The read state is active when MCR[PGM] or MCR[ERS] are high and high-voltage operation is ongoing (read-while-write).

### NOTE

Reads done to the partition(s) being operated on (either erased or programmed) result in an error and the MCR[RWE] bit is set.

- The read state is active when MCR[PGM] and MCR[PSUS] are high (program suspend).
- The read state is active when MCR[ERS] and MCR[ESUS] are high and MCR[PGM] is low (erase suspend).

In embedded flash memory, flash core reads return 256 bits (1 page). Register reads return 32 bits of data.

### NOTE

Flash core reads are done through the BIU. In many cases the BIU does read page buffering to allow sequential reads to be done with higher performance. This could provide a data coherency issue that must be handled with software. Data coherency may be an issue after a program or erase operation, as well as UTest NVM block operations.

In user mode, registers may be written. Array may be written to do interlock writes.

Register reads to unmapped register address space return all zeroes.

Register writes to unmapped register address space have no effect.

Interlock writes that are attempted during a high-voltage operation (MCR[EHV] = 1 or MCR[DONE] = 0) will result in the interlock write being ignored, and address and data will not be updated.

### NOTE

Care must be taken when doing 32-bit interlock writes. Performing two 32-bit interlock writes to the same word location is not supported. In addition, mixing 32-bit interlock writes with 64-bit interlock writes to the same double-word location is not supported. If these combinations are done, and a program operation is executed, the result will be MCR[PEG] = 0. See the Module Configuration Register (MCR) section for more information.

## 26.6.1.2 Program

A flash memory program sequence operates on any page within the flash core. Within a page, up to eight words may be altered in a single program operation. Also, up to four pages can be altered in a single program operation. Whenever the array is programmed, the ECC bits also get programmed. ECC is handled on a 64-bit boundary. Thus, if only one word in any given 64-bit ECC segment is programmed, the adjoining word (in that segment) should not be programmed, since ECC calculation has already completed for that 64-bit segment. Attempts to program the adjoining word will probably result in an operation failure. It is recommended that all programming operations be from 64 bits to 1024 bits, and be 64-bit aligned. The programming operation should completely fill selected ECC segments within the page. Only one program is allowed per 64-bit ECC segment between erases.

### Warning

In rare cases over-programming of a 64-bit ECC segment may be done (EEPROM emulation).

Programming changes the value stored in an array bit from logic 1 to logic 0 only. Programming cannot change a stored logic 0 to a logic 1.

### NOTE

If a logic 0 is attempted to be over-programmed by a logic 1, the resulting operation will fail ( $\text{MCR}[\text{PEG}] = 0$ ), and the 0's that are interlocked will be merged (ORed) with 0's that are already present in the 64-bit ECC segment, unless the block is designated as an Over-Program Protected block.

Addresses in locked/disabled blocks cannot be programmed. Values may be programmed in any or all of eight words, within a page, with a single program sequence. Page-bound words have addresses which differ only in address bits [4:2]. Up to four pages can be programmed at once on a quad-page boundary, which differ only in address bits [6:5]. The program operation consists of the following sequence of events:

1. Change the value in the  $\text{MCR}[\text{PGM}]$  bit from a 0 to a 1.

### NOTE

Ensure the block that contains the address to be programmed is unlocked.

2. Write the first address to be programmed with the program data. The embedded flash memory latches address bits [22:7] and SoC-specific UTest NVM enable at this time. The embedded flash memory latches data written as well. This write is referred to as

a program data interlock write. An interlock write may be done as a 64-bit transaction or a 32-bit transaction. Refer to the Flash Memory Controller chapter for information on the size of writes that are allowed.

3. If more than one word or doubleword is to be programmed, write each additional address in the page with data to be programmed. This is referred to as a program data write. The embedded flash memory ignores address bits [22:7] and SoC-specific UTest NVM enable for program data writes. All unwritten data words default to 0xFFFF\_FFFF.
4. Write a logic 1 to the MCR[EHV] bit to start the internal program sequence or skip to step 9 to terminate.
5. Wait until the MCR[DONE] bit goes high.

### NOTE

Since MCR[DONE] clears with MCR[EHV] being set, it may not be possible for software to read MCR[DONE] as a 0 prior to this step, depending on the operation selected.

6. Confirm MCR[PEG] = 1.
7. Write a logic 0 to the MCR[EHV] bit.
8. If more addresses are to be programmed, return to step 2.
9. Write a logic 0 to the MCR[PGM] bit to terminate the program sequence.

The first write after a program is initiated determines the quad-page address to be programmed. Program may be initiated with the 0 to 1 transition of the MCR[PGM] bit or by clearing the MCR[EHV] bit at the end of a previous program. This first write is referred to as an interlock write. The interlock write determines if the UTest NVM or normal array space is to be programmed by sampling SoC-specific UTest NVM enable and causing MCR[PEAS] to be set/cleared.

In the case of an erase-suspended program, the values in MCR[PEAS] may be modified via the program interlock write, enabling erase-suspended programs to and from UTest NVM space.

An interlock write must be performed before setting MCR[EHV]. A program sequence may be terminated by clearing MCR[PGM] prior to setting MCR[EHV].

After the interlock write, additional writes affect the data to be programmed at the word location determined by address bits [4:2], as well as the page location within a 1024-bit segment (determined by address bits [6:5]). Unwritten locations default to a data value of 0xFFFF\_FFFF. If multiple writes are done to the same location, the data for the last write is used in programming.

While DONE is low, EHV is high, and PSUS is low, then EHV may be cleared, resulting in a program abort. A program abort forces the embedded flash memory to step 8 of the program sequence. An aborted program results in PEG being set low, indicating a failed operation. The data space being operated on before the abort contains indeterminate data. A program sequence may not be aborted while in program suspend.

### **Warning**

Aborting a program operation leaves the flash core addresses being programmed in an indeterminate data state. This may be recovered by executing an erase on the affected blocks.

#### **26.6.1.2.1 Program software locking**

A software mechanism is provided to independently lock/unlock blocks against program and erase.

Software locking is done through the LOCK0, LOCK1, LOCK2, and LOCK3 registers. These may be written through register writes, and may be read through register reads.

#### **26.6.1.2.2 Program hardware locking**

Hardware locking which only affects the program operation is also available for UTest, 16 KB, 32 KB, 64 KB, and 256 KB blocks.

#### **26.6.1.2.3 Program suspend/resume**

The program sequence may be suspended to allow read access to the flash core. It is not possible to erase during a program suspend, or to program during a program suspend. These operations are prevented by register locking described in the Module Configuration Register (MCR) section. Read-while-write operation may also be used to read the array during a program sequence, providing the read is to a different partition.

A program suspend can be initiated by changing the value of the MCR[PSUS] bit from a 0 to a 1. MCR[PSUS] can be set high at any time when MCR[PGM] and MCR[EHV] are high. A 0 to 1 transition of MCR[PSUS] causes the embedded flash memory to start the sequence to enter program suspend, which is a read state. MCR[DONE] must become a logic level 1 before the embedded flash memory is suspended. At this time flash core reads may be attempted. Once suspended, the flash core may only be read. During suspend, all reads to flash core locations targeted for program, and blocks targeted for erase, return indeterminate data.

The program sequence is resumed by writing a logic 0 to MCR[PSUS]. MCR[EHV] must be set to a 1 before clearing MCR[PSUS] to resume operation. When the operation resumes, the embedded flash memory continues the program sequence from one of a set of predefined points. This may extend the time required for the program operation.

#### NOTE

Repeated suspends at a high frequency may result in the operation not completing normally. Although suspend frequency is not limited, enabling at least 20  $\mu$ s between suspend resume and future suspend requests improve the opportunity for the flash to complete the operation successfully.

#### 26.6.1.2.4 Over-program protection enable

One-time programming can be enabled on a block basis. In an over-program protection enabled block, any doubleword which has already been programmed cannot be programmed again. The over-program protection enable does not affect erase operation. Attempts to over-program will result in MCR[PEG] being cleared. If any doubleword within the quad-page has an over-program protection violation, MCR[PEG] will be cleared, and no doublewords will be programmed.

One-time programming can be enabled for 16 KB, 32 KB, 64 KB, or 256 KB blocks.

Over-program protection is enabled by sideband signals, and if enabled, the program operation will be modified to check for programmed bits prior to doing a high-voltage program event.

#### 26.6.1.2.5 Successful program address

To enable the SoC to create logic to authenticate operations with a program (such as in a diary operation), the flash module provides the last successful address programmed as a sideband signal. This value will be held until the next successful program. A successful program is defined as a program operation of data that is not all 1's to an unlocked block, and the operation results in MCR[PEG] returning a 1. If any doubleword within the pages being programmed is interlocked with all 1's, the sideband signal will not be updated. An address of all 1's, and each of the block size selects selected, is the default (and invalid) address after reset.

### 26.6.1.3 Erase

Erase changes the value stored in all bits of the selected block(s) to logic 1. An erase sequence operates on any combination of blocks in the main address space. The erase sequence is fully automated within the flash memory. Blocks to be erased must be selected prior to initiating the erase sequence. Locked/disabled blocks cannot be erased. If multiple blocks are selected for erase during an erase sequence, the blocks are erased sequentially starting with the lowest numbered block and terminating with the highest (low first, mid second, high last, 16 KB first, 32 KB second, 64 KB third, last blocks are 256 KB). The erase sequence consists of the following events:

1. Change the value in the MCR[ERS] bit from 0 to 1.
2. Select the block or blocks to be erased by writing ones to the appropriate registers in SEL0, SEL1, SEL2, or SEL3 registers.

#### NOTE

Lock and Select are independent. If a block is selected and locked, no erase occurs.

3. Write to any address in flash memory. This is referred to as an erase interlock write. An erase interlock write to UTest NVM space is not allowed if sealed (since erase is not allowed in the UTest NVM space when sealed).
4. Write a logic 1 to the MCR[EHV] bit to start an internal erase sequence or skip to step 9 to terminate.
5. Wait until the MCR[DONE] bit goes high.

#### NOTE

Since MCR[DONE] clears with MCR[EHV] being set, it may not be possible for software to read MCR[DONE] as a 0 prior to this step, depending on the operation selected.

6. Confirm MCR[PEG] = 1.
7. Write a logic 0 to the MCR[EHV] bit.
8. If more blocks are to be erased, return to step 2.
9. Write a logic 0 to the MCR[ERS] bit to terminate the erase.

After setting ERS, one write, referred to as an interlock write, must be performed before EHV can be set to a 1. Data words written during erase sequence interlock writes are ignored. The erase sequence may be terminated by clearing ERS before setting EHV.

An erase operation may be aborted by clearing EHV, assuming DONE is low, EHV is high, and ESUS is low. An erase abort forces the embedded flash memory to step eight of the erase sequence. An aborted erase results in PEG being set low, indicating a failed operation. The block(s) being operated on before the abort contain indeterminate data. An erase sequence may not be aborted while in erase suspend.

### 26.6.1.3.1 Erase software locking

Software Locking affect erase operation. For details on this see [Program software locking](#).

### 26.6.1.3.2 Erase hardware locking

Hardware locking which only affects the erase operation is also available for UTest, 16 KB, 32 KB, 64 KB, and 256 KB blocks.

### 26.6.1.3.3 Erase suspend/resume

The erase sequence may be suspended to allow read access to the flash core. The erase sequence may also be suspended to program (Erase-Suspended Program) the flash core. A program started during erase suspend can in turn be suspended. Only one erase suspend and one program suspend are allowed at a time during an operation. It is not possible to erase during an erase suspend, or program during a program suspend. During suspend, all reads to flash core locations targeted for program and blocks targeted for erase return indeterminate data.

Read-while-write operation may also be used to read the array during an erase sequence, provided the read is to a partition not selected for erase.

An erase suspend can be initiated by changing the value of the MCR[ESUS] bit from a 0 to a 1. MCR[ESUS] can be set to a 1 at any time when MCR[ERS] and MCR[EHV] are high and MCR[PGM] is low. A 0 to 1 transition of MCR[ESUS] causes the embedded flash memory to start the sequence which places it in erase suspend. MCR[DONE] must become a logic level 1 before the embedded flash memory is suspended and further actions are attempted. Once suspended, the array may be read or a program sequence may be initiated (erase-suspended program). Before initiating a program sequence, MCR[EHV] must first be cleared. If a program sequence is initiated, the values of SoC-specific UTest NVM enable is recaptured. Once the erase-suspended program is completed, the value of PEAS is returned to its erase value. Flash core reads that occur while MCR[ESUS] = 1 from the block(s) being erased will return indeterminate data.

The erase sequence is resumed by writing a logic 0 to MCR[ESUS]. MCR[EHV] must be set to a 1 and MCR[PGM] must be cleared (in the event of an erase-suspended program) before MCR[ESUS] can be cleared to resume the operation. The embedded flash memory continues the erase sequence from one of a set of predefined points. This may extend the time required for the erase operation.

**NOTE**

1. In an erase-suspended program, programming flash core locations in blocks which were being operated on will respond by completing the operation with a fail code (MCR[PEG] = 0). Programming voltages will not be applied to the memory array in this case.
2. Repeated suspends at a high frequency may result in the operation not completing normally. Although suspend frequency is not limited, enabling at least 5ms between suspend resume and future suspend requests improve the opportunity for the flash to complete the operation successfully.

**26.6.2 UTest mode**

UTest mode is a mode into which customers can put the embedded flash memory so as to do specific tests that check the integrity of the embedded flash memory.

**26.6.2.1 Array integrity self check**

The Array Integrity (AI) operation is a flash-specific self-test feature in which a MISR signature value is generated from data read from selected flash blocks. After the operation is complete, customer code compares the resulting MISR signature to the expected value to determine if an incorrect read or ECC detection occurred.

Array integrity operations are fully contained within the flash module. Results of Array integrity operations are not reported beyond the boundary of the flash module.

During array integrity test, user mode array reads are ignored to ensure the array integrity operation is not corrupted. User mode array reads may be executed if suspended or at a breakpoint.

AI read operations are executed using a predefined address sequence selected via the UT0[AIS] register field value. The data to be read is customer-specific, e.g., user program code that has been programmed into the flash memory. Any random or nonrandom code is valid. The expected MISR signature is calculated based on the specific data to be read.

Note that array integrity MISR signature calculations are performed after ECC detection and correction so correctable ECC events do not cause the MISR signature to deviate from the expected value.

The Array integrity check consists of the following sequence:

1. Enable UTest mode by setting the UT0[UTE] bit to 1.
2. Select one or more blocks for an array integrity check by writing 1's to the appropriate bits in the SEL0 – SEL3 registers. Blocks selected for AI test do not need to be unlocked.

Flash blocks that have not been selected are still read as part of the array integrity sequence to enable full transition coverage. Reads on unselected blocks are not captured in the MISR. Selecting fewer blocks may not result in a faster array integrity execution time, depending on the combinations of blocks selected and the sequence.

Blocks protected with the Test Mode Disable Seal are still read as part of the array integrity sequence. The resulting read on sealed blocks is not captured in the MISR, but the Single Bit Correction, Double Bit Detection and breakpoints are still honored.

### NOTE

It is not possible to do array integrity operations on the UTest NVM block.

3. If desired, set the UT0[AIS] bit to 1 for sequential addressing only.

For normal integrity checks of the flash memory, sequential addressing is recommended. If it is required to more fully check the read path (in a diagnostic mode), it is recommended that UT0[AIS] be left at 0, to use the address sequence that checks the read path more fully, and examine read transitions. This sequence takes more time.

4. Seed the MISR registers (UM0 — UM9) with desired values.
5. If breakpoints are desired, set UT0[AIBPE] to 1, and ensure that MCR[EER] and MCR[SBC] are cleared. If it is desired to break on single-bit correction, the UT0[SBCE] must be set.
6. Initiate AI by setting the UT0[AIE] bit to 1.

The array integrity operation may be aborted prior to UT0[AID] going high. This may be done by clearing the UT0[AIE] bit and continuing to the next step. It should be noted that in the event of an aborted array integrity check the MISR registers contain a signature for the portion of the operation that was completed prior to the abort, and are not deterministic. Prior to doing another array integrity operation, the UM0 – UM9 registers may need to be initialized to the desired seed value by doing register writes.

The array integrity operation may be suspended prior to UT0[AID] going high. UT0[AISUS] may be set to request an array integrity suspend. After the UT0[AISUS] bit is set, the user should wait for UT0[AID] bit to go high, which

indicates the flash has entered the suspend state, and normal reads to the flash may be done. After the UT0[AID] bit goes high, the UT0[AISUS] bit may be cleared to resume the array integrity sequence.

7. Wait until the UT0[AID] bit goes high, indicating that array integrity test is complete.
8. If breakpoints are enabled, check the UT0[NAIBP] bit. If set to 1, the MCR[EER], MCR[SBC], and ADDR registers may be checked to determine the cause of the break and the address of the break. Prior to resuming the operation, clear the MCR[SBC] or MCR[EER] bits, then resume the operation by clearing the UT0[NAIBP] bit. Continue to wait until the UT0[AID] bit goes high. If breakpoints are not enabled, or if the UT0[NAIBP] bit is low when the UT0[AID] bit goes high, the operation is complete. Continue to the next step.
9. Read values in the MISR registers (UM0 — UM9) to ensure correct signature.

### NOTE

Array integrity reads may be done to unselected (or non-present) locations. Reads done to these locations do not update the MISR, and do not update the MCR[EER] and MCR[SBC] error bits.

10. Write a logic 0 to the UT0[AIE] bit to complete array integrity test.

## 26.6.2.2 User margin read

User Margin Read is a flash-specific self-test feature that enables reads to be done at a Program margin or Erase margin level.

Margin reads are performed with an internal read reference voltage that has been adjusted, i.e., "margined" toward the threshold voltage being checked. The read reference voltage is either margined toward a 0 (programmed bit) or margined towards a 1 (erased bit), depending on the margin read operation selected.

User margin read is done using the array integrity interface, and has all the associated features of the array integrity interface (MISR and Breakpoints). User margin read is a self-timed event, and is independent of system clocks or wait states selected.

Margin read operations are fully contained within the flash module. Results of margin read operations are not reported beyond the boundary of the flash module.

During margin read operations, user mode array reads are ignored to ensure the operation is not corrupted. User mode array reads may be executed if suspended or at a breakpoint.

ECC corrections and detections are noted during the user margin read test. Note that margin read MISR signature calculations are performed *after* ECC detection and correction so correctable ECC events do not cause the MISR signature to deviate from the expected value.

The data to be read is customer-specific, e.g., user program code that has been programmed into the flash memory. Any random or non-random code is valid. The expected MISR signature is calculated based on the specific data to be read. After the operation is completed the margin read results can be checked by reading the MCR[EER] and MCR[SBC] bits to determine if zero, one, or two bits are being detected by the margin read, and comparing the generated MISR signature to the expected value.

The use model for margin read is in the event of a user-detected single bit correction (through user reads). A margin read may be done to check for a possible second bit falling within the selected margin levels.

The procedure for doing margin reads is:

1. Enable UTest mode by setting the UT0[UTE] bit to 1.
2. Select one or more blocks for margin read check by writing 1's to the appropriate bits in SEL0 – SEL3 registers. Blocks selected for margin read do not need to be unlocked.

Flash blocks that have not been selected are still read as part of the margin read sequence to enable full transition coverage. Reads on unselected blocks are not captured in the MISR. Selecting fewer blocks does not result in a faster margin read execution time.

Blocks protected with the Test Mode Disable Seal are still read as part of the margin read sequence. The resulting read on sealed blocks is not captured in the MISR, but the Single Bit Correction, Double Bit Detection and breakpoints are still honored.

### NOTE

It is not possible to do margin read operations on the UTest NVM block.

3. Set the UT0[AIS] bit to 1 for sequential addressing only.
4. Seed the MISR registers (UM0 — UM9) with desired values.
5. If breakpoints are desired, set UT0[AIBPE] to 1, and ensure that MCR[EER] and MCR[SBC] are cleared. If it is desired to break on single-bit correction, the UT0[SBCE] bit must be set to 1.
6. Initiate margin read by setting the UT0[MRE] bit to 1.
7. Select either one's margin or zero's margin by setting the UT0[MRV] bit to the appropriate value.
8. Set the UT0[AIE] bit.

During margin read operations, with UT0[AID] low, it is not recommended to attempt write operations to the MCR[SBC] and MCR[EER] bits. It is recommended that these bits only be written during suspend, breakpoints, or at completion of the Margin Read operation.

9. Wait until the UT0[AID] bit goes high, indicating that margin read test is complete.

If breakpoints were enabled or a suspend was requested during margin read, the operation may be at a breakpoint or a suspend state. See Step 8 in section [Array integrity self check](#) for more information.

10. Read values in the MISR registers (UM0 — UM9) to ensure correct signature.

#### NOTE

Margin reads may be done to unselected (or non-present) locations. Reads done to these locations do not update the MISR, and do not update the MCR[EER] and MCR[SBC] error bits.

11. Write a logic 0 to the UT0[AIE] bit.

## 26.7 Initialization information

A reset is the highest priority operation for the embedded flash memory and terminates all other operations.

The embedded flash memory uses reset to initialize register and status bits to their default reset values. If the embedded flash memory is executing a program or erase operation (PGM or ERS = 1) and a reset is issued, the operation is aborted and the embedded flash memory disables the high-voltage logic without damage to the high-voltage circuits. Reset aborts all operations and forces the embedded flash memory into user mode ready to receive accesses.

After reset is requested, MCR[DONE] goes low, and remains low during reset and reset recovery. At the end of reset recovery, MCR[DONE] transitions from a 0 to a 1.

After reset is completed, register reads may be done, although it should be noted that registers that require updating from UTest NVM information, or other inputs, may not read updated values until MCR[DONE] transitions high.

During reset recovery, register writes are not allowed until the MCR[DONE] bit transitions high to indicate reset recovery is completed.

### **Warning**

Resetting during a program or erase operation leaves the flash core blocks being programmed or erased in an indeterminate data state. This may be recovered by executing an erase on the affected blocks.

## Chapter 27

# Analog Modules Overview

### 27.1 Introduction

This chip has the following modules for the primary purpose of analog measurement:

- Two EQADC modules, each containing two internal ADCs
- Four Sigma-Delta (SD) ADC modules
- Two Temperature Sensors

### 27.2 EQADC subsystem

The integration of the two EQADC modules on this chip, EQADC\_A and EQADC\_B, is orthogonal except for the connection of the ADCs to specific external pins and internal channels.

The following diagram shows the connections of the two EQADCs to other on-chip components and external pins.

Figure 27-1. EQADC subsystem

## 27.3 SDADC connections to other modules

The integration of the four SDADC modules on this chip is orthogonal except for the connection of the ADCs to specific external pins and internal channels.

Each SDADC module:

- has an independent digital interface with register interfaces, control hardware, DMA and interrupt requests, and so on
- connects to a subset of external pins that also connect to an eQADC module
- connects to eTPU channels to support:
  - conversion result interrupt and DMA requests and flag to eTPU (with hardware gating)
  - high/low conversion limit checking with interrupt request and flag to eTPU

The following diagram shows the connections of an SDADC module to other on-chip components and external pins.

NOTE: SDADC\_4 has a 4:1 differential or 8:1 single-ended mux.

**Figure 27-2. SDADC connections to other modules**

# Chapter 28

## Sigma Delta Analog-to-Digital Converter (SDADC) Digital Interface

### 28.1 Chip-specific SDADC information

This chip has four instances of the SDADC module: SDADC\_1, SDADC\_2, and SDADC\_3, and SDADC\_4.

The following table summarizes varying features among the instances.

**Table 28-1. SDADC instance channels and muxes**

| Instance                     | # channels | Channels       | Single-ended input mux | Differential input mux |
|------------------------------|------------|----------------|------------------------|------------------------|
| SDADC1, SDADC_2, and SDADC_3 | 4          | AN[0] to AN[3] | 4:1                    | 2:1                    |

#### 28.1.1 SDADC triggers and synchronous start

Each SDADC instance can be triggered to start a conversion either by a software write to [Software Trigger Key Register \(SDADC\\_STKR\)](#) or by a hardware trigger input selected in [Module Configuration Register \(SDADC\\_MCR\)](#) by writing the [TRIGSEL](#) field. See [Hardware triggering](#) for more information about triggering SDADC instances.

To support the synchronous start of all SDADC instances, the trigger output of each instance connects as a trigger input to every other instance.

**Figure 28-1. SDADC simultaneous start connectivity**

Additional hardware trigger inputs connect to eTPU channels. The following table shows all of the hardware trigger inputs for each SDADC instance.

### Table 28-2. SDADC trigger inputs

## 28.1.2 Connections among SDADCs and eTPUs

For information about SDADC and eTPU connections, see:

- [SDADC triggers and synchronous start](#)
- [SDADC connections to other modules](#)
- SIU details about the mapping of DMA/interrupt gating and mux advance inputs as well as the mapping of end-of-conversion and watchdog flag outputs

## 28.2 Introduction

The Sigma-Delta Analog-to-Digital Converter (SDADC) digital interface block controls the on-chip SDADC and holds control and status registers accessible for application. It provides accurate conversion data for a wide range of applications.

## 28.3 Overview

The SDADC digital interface block provides all control information for operating mode selection (single-ended or differential), analog input gain, decimation rate, high-pass filter enable, etc. It also generates the bias controls for common mode voltage selection, to bias the positive and negative terminals to different voltage levels (for example, half scale bias, reference ground, reference supply) for diagnostics. It generates the analog multiplexer control signals for the selected channels. To assist synchronous operation across multiple ADC blocks, hardware trigger support is implemented to start data conversion.

The following figure depicts the block diagram of an SDADC and its digital control block.

Figure 28-2. SDADC block diagram

## 28.4 Features

The features of the SDADC are as follows:

- 16-bit data resolution output
- Single-ended input or differential input mode of operation
- Programmable wraparound mechanism for both modes of operation

- Configurable trigger sources: hardware or software
- Configurable initial entry and wraparound values for the loop
- Configurable biasing for negative input terminal in single-ended mode
- Gain and offset calibration support using fixed bias for input terminals
- Programmable decimation rate
- Programmable gain for analog inputs
- Optional high-pass filter for pure AC application
- Hardware trigger support for synchronous operation of multiple SDADC blocks
- Trigger event output generation by software
- Programmable FIFO structure for storing up to 16 datawords of 16-bit converted data
- Interrupt/DMA request generation based on various conditions:
  - Data buffer above threshold
  - Data buffer overrun
  - Watchdog (WDG) crossover event
- Programmable threshold range watchdog support
- Low consumption mode
- Optional conversion process halt mechanism on SoC debug request

## 28.5 Modes of operation

This section describes the different operation modes of the SDADC. When exiting reset, the mode of operation is determined by the Module Configuration Register (MCR).

### 28.5.1 Differential input mode

This mode is entered by negating the MCR[MODE] bit. In this mode, a pair of analog inputs are connected to positive and negative terminals of ADC modulator. In order to support gain and offset calibration for diagnostics, it is possible in this mode to select fixed bias voltages to both input terminals.

### 28.5.2 Single-ended input mode

This mode is entered by asserting the MCR[MODE] bit. In this mode, the negative input terminal is biased with a fixed voltage based on selection information in MCR, and the other analog input is connected to the selected external analog channel.

## 28.6 External signal description

The following table shows the list of signals driven by external pins. See the chip-specific details about SDADC signals and package pinouts for information about signal muxing and availability external to the chip.

**Table 28-3. Signal properties**

| Name    | Function                                                          | I/O | Reset | Pull-up |
|---------|-------------------------------------------------------------------|-----|-------|---------|
| AN[0:7] | Single-ended analog inputs or Differential pairs of analog inputs | I   | —     | —       |
| VREFP   | Voltage reference for SDADC                                       | I   | —     | —       |
| VREFN   | Ground reference for SDADC                                        | I   | —     | —       |
| AVDD    | Analog voltage supply for SDADC                                   | I   | —     | —       |
| AVSS    | Analog ground supply for SDADC                                    | I   | —     | —       |
| DVDD    | Digital voltage supply for SDADC                                  | I   | —     | —       |
| DVSS    | Digital ground supply for SDADC                                   | I   | —     | —       |

## 28.7 Memory map and register definition

This section provides the memory map for the SDADC block.

**SDADC memory map**

| Address offset (hex) | Register name                                   | Width (in bits) | Access | Reset value | Section/ page               |

**28.7.2 Channel Selection Register (SDADC\_CSR)**

The Channel Selection Register (CSR) selects analog inputs AN[0:7] to be connected to positive and negative terminals of the SDADC and controls the biasing of analog inputs to half-scale bias through 100 kOhm resistance.

Address: 0h base + 4h offset = 4h

| 21–23<br>ANCHSEL_WRAP | Analog Channel Selection Wraparound Value (ANCHSEL_WRAP)<br><br>When in wraparound mode, this field indicates the maximum value of the wraparound counter, after which it will wrap around back to initial value 000. This value should be programmed before enabling wraparound mechanism (MCR[WRMODE] = 1).                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |         |                         |                         |                         |                         |   |   |     |       |       |     |       |       |     |       |       |     |       |       |     |       |       |     |       |       |     |       |       |     |       |       |   |     |       |         |     |       |         |     |       |         |     |       |         |     |       |         |     |       |         |     |       |         |     |       |         |   |     |     |       |       |

**28.7.3 Reset Key Register (SDADC\_RKR)**

The Reset Key Register (RKR) is the target for a predefined key write operation used to reset the SDADC to start a fresh conversion.

Address: 0h base + 8h offset = 8h

|--------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0–15<br>Reserved   | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                   |
| 16–31<br>RESET_KEY | Reset Key<br>This field, when written with 5AF0h, is used to generate the reset for the SDADC block and to reload the internal counter with the start value programmed in OSDR. Any write access to this register which is different from the predefined key is ignored. Read access will always return the inverted key. |

## 28.7.4 Status Flag Register (SDADC\_SFR)

The Status Flag Register (SFR) contains status and flag bits. These bits are set by hardware and reflect the status of the SDADC and indicate the occurrence of events that may generate an interrupt or a DMA request. Software can clear some flags by writing '1' to those bits. Writing a '0' to a flag has no effect.

**SDADC\_SFR field descriptions (continued)**

| Field      | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
|------------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31<br>DFFF | <p>Data FIFO Full Flag</p> <p>This bit is set when the number of converted datawords in the FIFO is equal to or more than the number indicated by FCR[FTHL D]. Software can clear this bit by writing '1' to it. This bit is also cleared by an acknowledgement from the DMA controller when DMA request generation is selected. This bit remains set if software or DMA failed to clear the condition that caused this flag setting. Even if DFFF is set, datawords will continue to be received until an overrun condition occurs. Datawords will not be received if the converted data is not valid (CDVF = 0).</p> <p><b>NOTE:</b> Whenever MCR[EN] is cleared in order to stop the SDADC or change the channel configuration, it is necessary to also clear the RSER[DFFDIRE] bit alongwith. Similarly if DMA or software is too slow in not reading the FIFO datawords resulting in DFFF condition it is advisable to stop the SDADC by clearing the MCR[EN] followed by clearing of RSER[DFFDIRE] bit. Both these action will ensure safe operation.</p> <p>0 The number of datawords in FIFO is less than the number indicated by FCR[FTHL D]<br/> 1 The number of datawords in FIFO is equal to or greater than the number indicated by FCR[FTHL D] at some point in time since this flag was last cleared</p> |

**28.7.5 Request Select and Enable Register (SDADC\_RSER)**

The Request Select and Enable Register (RSER) serves two purposes:

- Enables the flag bits in SFR to generate DMA requests or interrupt requests.
- Selects the type of request to generate.

Refer to the field descriptions for the type of requests that are supported.

Address: 0h base + 10h offset = 10h

**SDADC\_RSER field descriptions (continued)**

| Field | Description                                                            |
|-------|------------------------------------------------------------------------|
| 0     | Interrupt/DMA request is disabled when data FIFO full condition occurs |
| 1     | Interrupt/DMA request is enabled when data FIFO full condition occurs  |

**28.7.6 Output Settling Delay Register (SDADC\_OSDR)**

The Output Settling Delay Register (OSDR) provides a delay value to qualify the converted output data coming from the SDADC.

Address: 0h base + 14h offset = 14h

| 0–23<br>Reserved | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| 24–31<br>OSD     | Output Settling Delay<br>This field defines the delay to qualify the conversion data stored in CDR. Whenever the SDADC block is reset in order to start the conversion from a fresh state, an internal timer is loaded with this start value. The counter counts down with output clock $f_d$ until it reaches zero, and then it generates a flag which qualifies the converted data. The output clock $f_d$ is equal to $f_s / (2 \times \text{OSR})$ , where $f_s$ is the input sampling clock frequency. See the electrical specifications for the settling delays.<br><br><b>NOTE:</b> Refer to the $t_{\text{settling}}$ and $t_{\text{LATENCY}}$ parameters in the device datasheet for the minimum allowed output settling delay values. |

28.7.7 FIFO Control Register (SDADC\_FCR)

The FIFO Control Register (FCR) provides the ability to enable or disable the FIFO functionality, and to control the amount of available FIFO depth to be used.

NOTE

1. It is important to note that the FIFO depth is set at the factory and cannot be changed but the amount of available FIFO space actually used can be set by specifying the value in the FTHLD field. The FSIZE field indicates the amount of FIFO space available. By setting the value of FTHLD to be less than the FIFO depth indicated by FSIZE, the FIFO is considered to be full when the number of data words in the FIFO is equal or greater than FTHLD.
2. This register may be read at any time, but should only be written when SDADC is disabled (MCR[EN] = 0).

Address: 0h base + 18h offset = 18h

| 16–31<br>ST_KEY  | Software Trigger Key<br>This bitfield, when written with FFFFh, is used to generate a trigger event output which can be used to trigger conversions of multiple SDADC blocks synchronously depending on the chip's implementation. Any write access to this register which is different from the predefined key is ignored. Read access will always return 0000h. |

## 28.7.9 Converted Data Register (SDADC\_CDR)

The Converted Data Register (CDR) stores the converted data in the data FIFO.

The conversion result in the CDATA word is a 16-bit, signed value.

### NOTE

When SDADC\_MCR[PGAN]=111b (programmable gain is 16), the least significant bit of the conversion data in SDADC\_CDR[CDATA] is always 0.

Address: 0h base + 20h offset = 20h

**28.8 Functional description**

The SDADC has the following distinct available modes determined by fields in MCR:

- Differential input mode
- Single-ended input mode
- Low consumption mode

### 28.8.1 Differential input mode

Differential input mode is entered when the SDADC\_MCR[MODE] field is set to '0' and the SDADC\_MCR[EN] field is set to '1'. In differential input mode, a pair of analog inputs among AN[0:7] is connected to the input terminals of the SDADC modulator block. The module supports four differential pairs: AN[0,1], AN[2,3], AN[4,5], and AN[6,7].

The modulator block has two input terminals, positive (INP) and negative (INM). The selection of input pair depends on the SDADC\_CSR[ANCHSEL] field. The connectivity of each analog input in a given differential pair, whether it is connected to positive or negative terminal, is determined according to the Analog input AN[0:7] selection table in the Channel Selection Register description.

The differential input mode can also be used to perform gain and offset calibration, where the input terminals are biased with fixed voltages coming from the bias block.

### 28.8.2 Single-ended input mode

Single-ended input mode is entered by setting the SDADC\_MCR[MODE] and SDADC\_MCR[EN] fields to '1'. In this mode, one of the analog inputs among AN[0:7] is selected via the SDADC\_CSR[ANCHSEL] field and is connected to the positive terminal. The negative input terminal is biased with a fixed internal voltage. There are two internal bias voltages available: reference ground (VREFN) and half-scale bias (VREFP/2). The selection of this common mode voltage is controlled via the SDADC\_MCR[VCOMSEL] field.

### 28.8.3 Low consumption mode

This is the default mode after exiting from reset. This mode is exited by asserting the MCR[EN] field to enable the SDADC block. When data conversion is not required, the SDADC internal modulator can be put in low consumption mode to reduce power consumption.

### 28.8.4 Analog input multiplexing and bias support

The complete selection and connectivity of analog inputs AN[0:7] is based on the ANCHSEL field of CSR and the MODE and VCOMSEL bits of MCR, according to the Analog input AN[0:7] selection table in the Channel Selection Register description. Each analog input can be biased to half scale ( $AVDD/2$ ) via on-chip 100 k $\Omega$  resistance. This allows simple AC coupling to the external analog inputs through a capacitor. This biasing is applicable irrespective of whether analog channel is selected through multiplexer or not.

### 28.8.5 Programmable gain and decimation rate

All analog inputs can be configured to have a selectable input gain as defined in the PGAN field description in MCR. This means the input signal is sampled and the result is amplified by the factor determined by PGAN before providing the same to modulator.

The SDADC module is provided with a fixed input sampling clock  $f_s$ . The input signal is grossly oversampled by the modulator in order to reduce quantization noise. To support different passbands with a fixed sampling clock, a programmable decimation rate is implemented. The process of decimation, to eliminate redundant data at the output while retaining the necessary information, is controlled by the field PDR in MCR.

### 28.8.6 High-pass filter support

For pure AC applications, it is useful to remove any DC component in the input signal. An optional high-pass filter is implemented which can be enabled by asserting the MCR[HPFEN] field. The  $-3$  dB frequency of the filter is fixed (not programmable) and is specified in the device data sheet. This high-pass filter is implemented in the decimation filter logic of the SDADC.

### 28.8.7 Data conversion

The SDADC operates in a continuous conversion mode as soon as it is enabled. There is an inherent settling time required after SDADC startup before conversion data is considered valid.

#### NOTE

During that period, the Converted Data Valid Flag bit (SDADC\_SFR[CDVF]) reads '0'.

Settling time duration depends on the latency and output settling time specifications. To account for the settling time, an internal timer is implemented that counts down from a start value determined by the value of the SDADC\_OSDR[OSD] field.

The internal countdown timer is triggered by an SDADC reset, i.e., by writing the value 5AF0h to the SDADC\_RKR[RESET\_KEY] field.

### NOTE

An SDADC reset is required any time there is a change to the SDADC configuration (via changes to the SDADC\_MCR register settings), or a change to analog channel selection (via SDADC\_CSR register settings).

When the timer reaches '0', the SDADC\_SFR[CDVF] field is asserted and converted data is loaded into data FIFO on every rising edge of the output clock ( $f_d$ ).

Any write access to the SDADC\_MCR or SDADC\_CSR register causes the SDADC\_SFR[CDVF] flag to be cleared, indicating that data coming from SDADC is not valid. If the SDADC\_SFR[CDVF] flag is '0', the following flags are blocked from becoming asserted:

- Data FIFO Full Flag (SDADC\_SFR[DFFF])
- Data FIFO Overrun Flag (SDADC\_SFR[DFORF])

If the SDADC\_SFR[DFFF] bit is already set, the data FIFO is already full before SDADC\_SFR[CDVF] deassertion.

Wraparound Control Mechanism: Here a wraparound logic includes all analog channels of the input multiplexer from  $Ain("000")$  to  $Ain(CSR[ANCHSEL\_WRAP])$  in both Single ended and Differential ended mode in wraparound sequence triggered by hardware or software source:

- MCR[WRMODE] bit would enable or disable the wraparound mechanism. Clearing the WRMODE bit automatically switches FSM back to Software control mode.
- Every valid trigger advances the wraparound counter to next channel to be converted.
- Wraparound Counter: An internal wraparound counter which points to analog channel to be converted takes the initial entry value for the first loop of execution from CSR[ANCHSEL] while entering wraparound mode. From next loop onwards the counter wraparounds to default initial value "000". Maximum value of the counter (wraparound value) should be programmed in CSR[ANCHSEL\_WRAP] before entering wraparound mode. The definition of ANCHSEL and ANCHSEL\_WRAP is provided in the Analog input AN[0:7] selection table in the Channel Selection Register description.
- Upon entering or during wraparound mode user should take care to program ANCHSEL value less than ANCHSEL\_WRAP value; otherwise hardware would reject the new ANCHSEL value.

- Possible trigger sources:
  - SOURCE1 (Software Bit): writing to STKR.ST\_KEY at any time during the wraparound mode (irrespective of MCR[TRIGEN or TRIGSEL] setting) generates a trigger pulse. Each such trigger initiates a fresh conversion and advances the wraparound counter by one.

### NOTE

Care should be taken while programming the TRIGEN/TRIGSEL of each SDADC instance that no unintended simultaneous SW triggering of multiple instances happen.

- SOURCE2 (Hardware Trigger): Here external trigger output enabled by MCR[TRIGEN or TRIGEDSEL or TRIGSEL] before entering wraparound mode for selective or all SDADC instances provides trigger. Each such valid trigger initiates a fresh conversion and advances the wraparound counter by one. One of the hw\_trig\_in ports can be used to connect the external trigger output.
- Next channel number to be converted can be updated by software even in the middle of wraparound sequence execution. This can be done by rewriting CSR[ANCHSEL]. After CSR[ANCHSEL] is rewritten, the next trigger takes updated value and the wraparound counter would increment from the updated value.
- Current wraparound counter value can be read from the SFR[ANCHSEL\_CNT] bitfield.

## 28.8.8 Hardware triggering

Software Control Mechanism: SDADC conversion can be triggered by various hardware events coming from either external pins or internal timers. The field TRIGSEL of MCR selects which hardware event is to be used for triggering conversions. This trigger event, which is synchronous to the peripheral clock, is enabled by asserting MCR[TRIGEN]. As soon as a trigger event is detected, reset input of SDADC block is asserted synchronously for four cycles. This will ensure that SDADC starts from a fresh state when reacting to the input trigger event. The SDADC internal modulator must be enabled before enabling the trigger event — otherwise the trigger event will be ignored.

If the same trigger event is provided to multiple SDADC digital interface modules and the respective enable controls (TRIGEN bit MCR) are asserted, synchronous operation of multiple SDADC blocks can be achieved with output results being updated at the same time. Once the reset input is deasserted, the first valid conversion output is stored in data FIFO after a configurable delay determined by OSD[OSD].

It is also possible to generate a software trigger event output by a write access of STKR with a predefined key. This event output can be used as a trigger to achieve synchronous software start of multiple SDADC blocks.

In case of a hardware trigger, the skew/jitter will be less than 100 ns. It will be more than one ADC clock cycle due to synchronization. In case of a software trigger, all SDADCs start synchronous sampling.

Wraparound Control Mechanism: In wraparound control mode, hardware and software triggers are equally valid. The hardware trigger source should be selected before enabling the wraparound mode.

### **28.8.9 Interrupt/DMA request support**

The SDADC has one condition that generates interrupts only and another that generates interrupts or DMA request.

The DFFF field is asserted when the data FIFO full condition is detected, indicating that the number of converted datawords stored in data FIFO is equal to or greater than the value indicated by threshold determined by FCR[FTHLD]. The interrupt or DMA request is generated only when RSER[DFFDIRE] is asserted. RSER[DFFDIRS] selects whether a DMA request or an interrupt request is generated.

The data FIFO overrun flag (DFORF) indicates the FIFO overflow condition. Further converted datawords cannot be received and data is lost. The interrupt request is generated only when RSER[DFORIE] is asserted.

Apart from above, a WDG threshold crossover event can also generate an interrupt or DMA request.

If RSER[GDIGE] is set, all module interrupt/DMA requests are qualified only when an external global gating signal is asserted.

### **28.8.10 Gain calibration support**

To perform gain calibration, the following sequence needs to be applied.

1. Select differential mode of operation by writing MCR[MODE] to '0'.
2. Enable gain error calibration mode by writing MCR[GECEN] to '1'.
3. Configure the mux selection ANCHSEL field of CSR to '110'. This configuration will apply VREFP on positive terminal and VREFN on negative terminal.
4. Disable the bias on all input analog channels by writing ENBIAS field of CSR to 00h.

5. Disable the high-pass filter by deasserting MCR[HPFEN].
6. Generate a reset event by writing 5AF0h to RESET\_KEY of RKR.
7. Read the digital output (CDR[CDATA]) stored in FIFO after the output settling time. Expected output if there is no gain error is 0111\_1001\_1001\_1001b, corresponding to full positive scale after attenuation inserted by the internal filter ( $1 \times 0.95$ ). The measurement should be repeated to reduce contribution of noise during the calibration process.  $D_p$  is the average value of attenuated positive full scale given by  $D_p = \text{AVERAGE}(\text{CDR}[\text{CDATA}])$ .
8. Change the mux selection ANCHSEL field of CSR to '111'. This configuration will apply VREFN on positive terminal and VREFP on negative terminal.
9. Generate a reset event by writing 5AF0h to RESET\_KEY of RKR.
10. Read the digital output (CDR[CDATA]) stored in FIFO after the output settling time. Expected output if there is no gain error is 1000\_0110\_0110\_0110b, corresponding to full negative scale after attenuation inserted by the internal filter ( $-1 \times 0.95$ ). The measurement should be repeated to reduce contribution of noise during calibration process.  $D_n$  is the average value of attenuated negative full scale given by  $D_n = \text{AVERAGE}(\text{CDR}[\text{CDATA}])$ .
11. The SDADC calibrated gain can be calculated as:  

$$\text{Gain} = (D_p - D_n) / 2^{16}$$
12. The measured gain value can be used to nullify the gain errors in the digital output. For calibrated conversion, the data CDR[CDATA] provided by the SDADC should be normalized using the calculated gain:  $\text{CDATA}_{\text{norm}}$  is given by  $\text{CDATA}_{\text{norm}} = \text{CDR}[\text{CDATA}] / \text{Gain}$ .

### Note

- a. The gain error calibration should only be done with gain equal to '1' (in other words, PGAN = 000). Nevertheless, the calculated gain can be applied to normalized data also for conversion with  $\text{GAIN} > 1$ .
- b. MCR[GECEN] = 1 ensures the accurate gain error mode is enabled. This bit should be set both during calibration process and after calibration, for application data conversion. Application data conversion must then be normalized using the measured gain.
- c. The higher the number of full-scale conversion ( $D_p$ ,  $D_n$ ) done, the higher the rejection of noise during the calibration. The number of conversion is dependent on application noise. It is recommended to run at least 16 conversions when calculating an average value.

## 28.8.11 Offset calibration support

To perform offset calibration, the following sequence must be applied.

1. Select differential mode of operation by writing SDADC\_MCR[MODE] to '0'.
2. Configure the SDADC\_CSR[ANCHSEL] mux selection field to '100' or '101' as required.
  - a. SDADC\_CSR[ANCHSEL] = '100' in case of data conversion after calibration in "single ended mode with negative input= $V_{SS\_HV\_ADR\_D}$ "
  - b. SDADC\_CSR[ANCHSEL] = '101' in case of data conversion after calibration in "differential mode" and "single ended mode with negative input =  $(V_{DD\_HV\_ADR\_D} - V_{SS\_HV\_ADR\_D}) / 2$ "
3. Disable the bias on all input analog channels by writing ENBIAS field of CSR to 00h.
4. Disable the high pass filter by deasserting SDADC\_MCR[HPFEN].
5. Generate a reset event by writing 5AF0h to RESET\_KEY of RKR.
6. Read the digital output stored in FIFO after the output settling time.
7. The measured offset can be used to nullify the offset error in the digital output.  
Expected output is 00\_0000\_0000\_0000b. The SDADC offset can be calculated as:  
Offset = Expected Output – Actual Output

### Note

The offset must be calculated for each SDADC\_MCR[PGAN] field setting since it is expected to vary with gain configuration of SDADC.

## 28.9 Initialization information

To initialize the SDADC registers for data conversion, the following sequence is required.

1. Enable the SDADC by asserting MCR[EN].
2. Configure MCR to select the required mode, polarity, common mode voltage, input gain, and decimation rate.
3. Enable high-pass filter if required.
4. Select the required analog channel for data conversion. It is possible to select the bias for each channel for AC coupling applications.
5. Configure OSD delay according to SDADC startup time or latency from reset exit.
6. Generate a reset event by writing 5AF0h to RESET\_KEY of RKR. Otherwise, if data conversion need to be triggered by a hardware event, assert MCR[TRIGEN].

7. DFFF interrupt or DMA request will be generated after the data FIFO has reached threshold to indicate that data can be transferred.

### 28.9.1 Data conversion step

To acquire a data from SDADC, the following sequence is required:

1. Enable the SDADC by asserting MCR[EN].
2. Configure MCR to select the required mode, polarity, common mode voltage, input gain, and decimation rate.
3. Enable high-pass filter is required.
4. Select the required analog channel for data conversion. It is possible to select the bias for each channel for AC coupling applications.
5. Configure OSD delay according to SDADC required startup time or latency from reset exit.
6. Generate a reset event writing 5AF0h in RESET\_KEY field of RKR register.
7. Wait till FIFO empty flag DFEF of SFR register is clear.
8. Read data by CDATA of CDR register.

Repeat steps from 6 to 8 for new acquisitions.

#### NOTE

The time elapsed between reset event and Read data by CDATA field of CDR register are:

- Reset event <- -> Data Valid flag(CDVS) = Output settling Time delay (OSDR has to be set at least to 16) (Refer to the  $t_{\text{settling}}$  and  $t_{\text{LATENCY}}$  parameters in the device datasheet for the minimum allowed output settling delay values.).
- Data Valid flag <- -> Data FIFO is not empty =  $0.5 * \text{CLK\_Out} + 3 * \text{CLK\_In}$
- Data FIFO is not empty <- -> read Data (safety point) =  $2 * \text{CLK\_In}$ , where  $\text{CLK\_Out} = \text{CLK\_In} / (2 * \text{OSR})$

## Chapter 29

# Enhanced Queued Analog-to-Digital Converter (EQADC)

### 29.1 Chip-specific EQADC information

This chip has two instances of the EQADC module: EQADC\_A and EQADC\_B.

Each EQADC module:

- controls two independent Redundant Signed Digit (RSD) analog-to-digital (ADC) converter cores: ADC0 and ADC1.
- has an independent digital interface with register interfaces, control hardware, DMA and interrupt requests, and so on.

Chip-specific features of the EQADCs include:

- 24 dedicated external analog input pins to each EQADC module
- 16 pins shared between the two modules
- 6 additional pins share the dedicated EQADC\_B channel inputs for greater pinout flexibility
- No support for external converters or an external device; the SSI interface is not present
- Addition of a Burst Trigger Generator, which is described in the SIU chapter
- Addition of bias/diagnostic pull up/down in the pad cell to support sharing ADC pins with SDADC inputs
- Targets up to 1.5M Sample/s (ADC\_CLK=24 MHz) for differential conversions

The value of the external bypass between capacitor REFBYPC and VRL should be 100 nf.

**NOTE**

Due to legacy reasons, both ADC0 and ADC1 must be enabled for accurate conversion results.

**NOTE**

An 8 ms wait time from VDDA power up to enabling ADC is required to pre-charge the external 100 nf capacitor on REFBYPC pin. This time must be guaranteed by crystal startup time plus reset duration or user. The ADC internal bias generator circuit will start up after 10  $\mu$ s upon VRH/VRL and VDDA/VSSA power up and produces a stable/required bias current to the pre-charge circuit, but the current to other analog circuits are disabled until ADCs are enabled. As soon as the ADCs are enabled, the bias currents to all of analog circuits will be enabled.

### 29.1.1 EQADC connections to other modules

Each EQADC module:

- has internal channel connections with the Power Management Controller module.

#### 29.1.1.1 Sources of software and external hardware triggers

The EQADC supports software and external hardware triggers (via package pins) from the PIT-RTI, eTPU, and eMIOS modules to initiate transfers of commands from the CFIFOs to the on-chip ADCs.

#### 29.1.1.2 STAC server IDs

STAC server IDs are defined in [STAC server IDs](#) in the chip-specific eTPU information.

### 29.1.2 EQADC Stop mode entry

On this chip, SIUL\_HLT1[EQADCx] is the chip-level control for issuing a request to an EQADC instance to enter its Stop mode.

### 29.1.3 EQADC pre-gain control

On this chip, the analog ADC option to select x1, x2, or x4 pre-gain is available only for differential conversions. Single-ended conversions can use only x1 pre-gain.

The PRE\_GAIN field of the [Alternate Configuration 1-14 Control Registers \(ADC\\_ACR1-14\)](#) controls the selection.

### 29.1.4 CFIFO and RFIFO depth

Every CFIFO and RFIFO, including CFIFO0, has four entries.

### 29.1.5 EQADC pin pullup/pulldown control

This following table shows the analog and digital EQADC pins with pullup/pulldown control and the registers that provide the control.

**Table 29-1. EQADC pins with pullup/pulldown and control registers**

| Pin function | EQADC_A                        | EQADC_B                         | Pullup/pulldown control registers                                        |
|--------------|--------------------------------|---------------------------------|--------------------------------------------------------------------------|
| Analog       | ANA0 to ANA7<br>ANA16 to ANA23 | ANB0 to ANB7                    | <a href="#">ADC Pull Up/Down Control Register x (ADC_PUDCRx, x=0-39)</a> |
| Digital      | —                              | ANB8 to ANB23<br>ANB40 to ANB45 | <a href="#">Pad Configuration Register (SIU_PCRn)</a>                    |

### 29.1.6 EQADC pin-to-channel mapping

For both EQADC\_A and EQADC\_B, the following table shows the pin-to-channel mapping to show which signals go to which ADC.

**Table 29-2. EQADC\_A and EQADC\_B pin-to-channel mapping**

| Analog input pin on 416 MAPBGA package | Function                   | ADC number |         | EQADC_A channel number | EQADC_B channel number |
|----------------------------------------|----------------------------|------------|---------|------------------------|------------------------|
|                                        |                            | EQADC_A    | EQADC_B |                        |                        |
| ANA0-ANA23 <sup>1</sup>                | Single ended conversion    | 0, 1       | —       | 0-23                   | —                      |
| ANB0-ANB23                             | Single ended conversion    | —          | 0, 1    | —                      | 0-23                   |
| AN24-AN39                              | Single ended conversion    | 0, 1       | 0, 1    | 24-39                  | 24-39                  |
| —                                      | VRH                        | 0, 1       | 0, 1    | 40                     | 40                     |
| —                                      | VRL                        | 0, 1       | 0, 1    | 41                     | 41                     |
| —                                      | 50% (VRH-VRL) <sup>2</sup> | 0, 1       | 0, 1    | 42                     | 42                     |

*Table continues on the next page...*

**Table 29-2. EQADC\_A and EQADC\_B pin-to-channel mapping (continued)**

| Analog input pin on 416 MAPBGA package | Function                                        | ADC number |         | EQADC_A channel number | EQADC_B channel number |
|----------------------------------------|-------------------------------------------------|------------|---------|------------------------|------------------------|
|                                        |                                                 | EQADC_A    | EQADC_B |                        |                        |
| —                                      | 75% (VRH-VRL)                                   | 0, 1       | 0, 1    | 43                     | 43                     |
| —                                      | 25% (VRH-VRL)                                   | 0, 1       | 0, 1    | 44                     | 44                     |
| —                                      | Local bandgap 1220 mV                           | 0, 1       | —       | 45                     | —                      |
| ANA8                                   | ANWA <sup>3</sup>                               | 0, 1       | —       | 64-71                  | —                      |
| ANB8                                   | ANWB                                            | —          | 0, 1    | —                      | 64-71                  |
| ANA9                                   | ANXA                                            | 0, 1       | —       | 72-79                  | —                      |
| ANB9                                   | ANXB                                            | —          | 0, 1    | —                      | 23-79                  |
| ANA10                                  | ANYA                                            | 0, 1       | —       | 80-87                  | —                      |
| ANB10                                  | ANYB                                            | —          | 0, 1    | —                      | 80-87                  |
| ANA11                                  | ANZA                                            | 0, 1       | —       | 88-95                  | —                      |
| ANB11                                  | ANZB                                            | —          | 0, 1    | —                      | 88-95                  |
| ANA0 and ANA1                          | DANA0+ and DANA0-                               | 0, 1       | —       | 96                     | —                      |
| ANB0 and ANB1                          | DANB0+ and DANB0-                               | —          | 0, 1    | —                      | 96                     |
| ANA2 and ANA3                          | DANA1+ and DANA1-                               | 0, 1       | —       | 97                     | —                      |
| ANB2 and ANB3                          | DANB1+ and DANB1-                               | —          | 0, 1    | —                      | 97                     |

1. AN8x-ANx11 and ANx16-ANx19 have alternate functions when used with an external multiplexer.
2. After calibration, the 50% reference point reads approximately 20 mV below 50% (VRH-VRL). The 50% reference point should not be used to calibrate the EQADC. Use the 25% and 75% reference points to calibrate the EQADC.
3. This function is present when using an external multiplexer.
4. Select the desired PMC voltage using the channel select field [ADC\\_CS](#) of the [ADC\\_CS](#)

## 29.2 Introduction

### 29.2.1 Module overview

The Enhanced Queued Analog-to-Digital Converter (EQADC) block provides accurate and fast conversions for a wide range of applications. The EQADC provides a parallel interface to two on-chip analog-to-digital converters (ADCs), and a parallel side interface to one or more on-chip digital signal processing (DSP) modules (for example, a decimation filter). The two on-chip ADCs are architected to allow access to all the analog channels.

The EQADC transfers commands from multiple Command FIFOs (CFIFOs) to the on-chip ADCs. The multiple Result FIFOs (RFIFOs) can receive data from the on-chip ADCs or from an on-chip DSP module. Data from the on-chip ADCs can be routed to the side interface, processed by the on-chip DSP and then routed back through the side interface to the RFIFOs. The EQADC supports software and external hardware triggers from other blocks to initiate transfers of commands from the CFIFOs to the on-chip ADCs. It also monitors the fullness of CFIFOs and RFIFOs, and accordingly generates DMA or interrupt requests to control data movement between the FIFOs and the system memory, which is external to the EQADC.

### 29.2.2 Block diagram

[Figure 29-1](#) is the block diagram for the EQADC.

**Figure 29-1. EQADC Block Diagram**

Figure 29-1 shows the primary components inside the EQADC. The EQADC consists of the *FIFO Control Unit* which controls the CFIFOs and the RFIFOs, the *ADC Control Logic* which controls the two on-chip ADCs, and the *EQADC Parallel Side Interface* (EQADC PSI) which allows communication with on-chip eQADC companion<sup>1</sup> modules. There are 6 CFIFOs and 6 RFIFOs, each with 4 entries, except CFIFO0 that can have 8 entries.

The *FIFO Control Unit* performs the following functions:

- It prioritizes the CFIFOs to determine what CFIFOs will have their commands transferred.

1. Depending on the device, companion modules may be DSP modules, decimation filters, or any other processing block.

- Supports software and hardware triggers to start command transfers from a particular CFIFO.
- Decodes command data from the CFIFOs, and accordingly, sends these commands to one of the two on-chip ADCs.
- Decodes result data from on-chip ADCs and transfers data to the appropriate RFIFO or to the parallel side interface.

The *ADC Control Logic* manages the execution of commands bound for on-chip ADCs. It interfaces with the CFIFOs via two 2-entry command buffers (CBuffers) with abort control and with the RFIFOs and side interface via the *Result Format and Calibration Sub-Block*. The *ADC Control Logic* performs the following functions:

- Buffers command data for execution.
- Decodes command data and accordingly generates control signals for the two on-chip ADCs.
- Detects abort request, stores aborted commands and buffers immediate conversion commands.
- Formats and calibrates conversion result data coming from the on-chip ADCs.
- Generates the internal multiplexer control signals and the select signals used by the external multiplexers.

The EQADC PSI allows for a full duplex, synchronous, parallel communication between the EQADC and several on-chip companion modules.

Figure 29-1 also depicts data flow through the EQADC. Commands are contained in system memory in a user defined data structure. The most likely data structure to be used is a queue as depicted in the Figure 29-1<sup>2</sup>. Command data is moved from the command queue (CQueue) to the CFIFOs by either the host CPU or by the DMAC. Once a CFIFO is triggered and becomes the highest priority CFIFO using a certain CBuffer, command data is transferred from the CFIFO to the on-chip ADCs. The ADC executes the command, and the result is moved through the *Result Format and Calibration Sub-Block* to either the side interface or to the RFIFO. Data from the on-chip companion module bypasses the *Result Format and Calibration Sub-Block* and is moved directly to its specified RFIFO. When data is stored in an RFIFO, data is moved from the RFIFO by the host CPU or by the DMAC to a data structure in system memory depicted in the Figure 29-1 as a result queue (RQueue).

2. Command and result data can be stored in system memory in any user defined data structure. However, in this document it will be assumed that the data structure of choice is a queue, since it is the most likely data structure to be used and because queues are the only type of data structure supported by the DMAC.

For users familiar with the QADC, the EQADC system upgrades the functionality provided by that block. See [EQADC versus QADC](#) for a comparison between the EQADC and QADC.

### 29.2.3 Features

The EQADC block includes these distinctive features:

- Two independent on-chip RSD Cyclic ADCs
  - 8, 10, and 12 bits Resolution
  - Differential conversions
  - Differential channels include variable gain amplifier for improved dynamic range (x1; x2; x4)
  - Differential channels include programmable pull-up and pull-down resistors for biasing and sensor diagnostics (200k ohms; 100k ohms; 5k ohms)
  - Sample times of 2 (default), 8, 64 or 128 ADC clock cycles
  - Provides time stamp information when requested
  - Parallel interface to EQADC CFIFOs and RFIFOs
  - Supports both right-justified unsigned and signed formats for conversion results
  - The REFBYPC pin stabilizes one of internal generated reference
  - Temperature sensor
  - Ability to measure directly Vdd
- Automatic application of ADC calibration constants
  - Provision of reference voltages (25%VREF and 75%VREF) for ADC calibration purposes
- 40 input channels available to the two on-chip ADCs
- 4 pairs of differential analog input channels
- Parallel Side Interface to communicate with several on-chip companion modules
- STAC bus to import an alternative timebase to the internal time stamp
- Priority Based CFIFOs

- Supports six CFIFOs with fixed priority. The lower the CFIFO number, the higher its priority. When commands of distinct CFIFOs are bound for the same CBuffer, the higher priority CFIFO is always served first.
- Immediate conversion command feature with conversion abort control
- Streaming mode operation of CFIFO0 to execute some commands several times
- Supports software and several hardware trigger modes to arm a particular CFIFO
- Generates interrupt when command coherency is not achieved
- External Hardware Triggers
  - Supports rising edge, falling edge, high level and low level triggers
  - Supports configurable digital filter
  - Supports controls to bypass the trigger digital filters
- Two Triggers operation mode for queue0
  - Additional internal trigger (not filtered) called Advance trigger that is used to enable the external trigger of queue0 and to control the loop behavior of CFIFO0
- Supports 4 to 8 external 8-to-1 muxes which can expand the input channel number from 40 to 96

## 29.3 Modes of operation

This section describes the operation modes of the EQADC.

### 29.3.1 Normal Mode

This is the default operational mode when the EQADC is not in background debug or stop mode.

### 29.3.2 Debug Mode

Upon a debug mode entry request, EQADC behavior will vary according to the status of the DBG field in [EQADC Module Configuration Register \(EQADC\\_MCR\)](#). If DBG is programmed to 0b00, the debug mode entry request is ignored. If DBG is programmed to 0b10 or to 0b11, the EQADC will enter debug mode.

During debug mode, the EQADC will not transfer commands from any CFIFOs, no null messages will be transmitted to the device, no data will be returned to any RFIFO, no hardware trigger event will be captured, and all EQADC registers can be accessed as in Normal mode. The latter implies that CFIFOs can still be triggered using software triggers, since no scheme is implemented to write-protect registers during debug mode. DMA and interrupt requests continue to be generated as in Normal Mode.

If at the time the debug mode entry request is detected, there are commands in the on-chip CBuffers that were already under execution, these commands will be completed but the generated results, if any, will not be sent to the RFIFOs until debug mode is exited. Commands whose execution has not started will not be executed until debug mode is exited.

The clock associated with an on-chip ADC stops, during its low phase, after the ADC ceases executing commands. The time base counter will only stop after all on-chip ADCs cease executing commands.

When exiting debug mode, the EQADC relies on the CFIFO operation modes and on the CFIFO status to determine the next command entry to transfer.

The EQADC internal behavior after the debug mode entry request is detected differs depending on the status of command transfers.

- No command transfer is in progress.

The EQADC immediately halts future command transfers from any CFIFO.

If a null message is being transmitted, EQADC will complete the serial transmission before halting future command transfers. If valid data (conversion result or data read from an ADC register) is received at the end of transmission, it will not be sent to an RFIFO until debug mode is exited.

If the null message transmission is aborted, the EQADC will complete the abort procedure before halting future command transfers from any CFIFO. The message of the CFIFO that caused the abort of the previous serial transmission will only be transmitted after debug mode is exited.

- Command transfer is in progress.

EQADC will complete the transfer and update CFIFO status before halting future command transfers from any CFIFO. Command transfers to the internal CBuffers are considered completed when a command is written to the buffers.

- Command/Null message transfer through serial interface was aborted but next serial transmission did not start.

If the debug mode entry request is detected between the time a previous serial transmission was aborted and the start of the next transmission, the EQADC will complete the abort procedure before halting future command transfers from any CFIFO. The message of the CFIFO that caused the abort of the previous serial transmission will only be transmitted after debug mode is exited.

### 29.3.3 Stop Mode

Upon a stop mode entry request detection, the EQADC progressively halts its operations until it reaches a static, stable state from which it can recover when returning to Normal mode. EQADC then asserts an acknowledge signal, indicating that it is static and that the clock input can be stopped. . The latter implies that, as long as the system clock is running, CFIFOs can still be triggered using software triggers, since no scheme is implemented to write-protect registers during stop mode.

If at the time the stop mode entry request is detected, there are commands in the on-chip CBuffers that were already under execution, these commands will be completed but the generated results, if any, will not be sent to the RFIFOs until stop mode is exited. Commands whose execution has not started will not be executed until stop mode is exited.

After these remaining commands are executed, the clock input to the ADCs and the bias generator circuit is stopped. The ADC clock stops during its low phase. The time base counter will only stop after all on-chip ADCs cease executing commands. Only then, the stop acknowledge signal is asserted. When exiting stop mode, the EQADC relies on the CFIFO operation modes and on the CFIFO status to determine the next command entry to transfer.

The EQADC internal behavior after the stop mode entry request is detected differs depending on the status of the command transfer.

- No command transfer is in progress

The EQADC immediately halts future command transfers from any CFIFO.

If a null message is being transmitted, EQADC will complete the transmission before halting future command transfers. If valid data (conversion result or data read from an ADC register) is received at the end of the transmission, it will not be sent to an RFIFO until stop mode is exited.

If the null message transmission is aborted, the EQADC will complete the abort procedure before halting future command transfers from any CFIFO. The message of the CFIFO that caused the abort of the previous serial transmission will only be transmitted after stop mode is exited.

- Command transfer is in progress

EQADC will complete the transfer and update CFIFO status before halting future command transfers from any CFIFO. Command transfers to the internal CBuffers are considered completed when a command is written to the buffers.

## 29.4 External signal description

### 29.4.1 Overview

The following is a list of external pins.

#### Note

At chip integration level, some of the digital and analog signals listed here might share pins or not be available to the chip. Refer to the Signals chapter for details.

**Table 29-3. External signals**

| Name      | Port  | Function                                                                | Reset state | Type   |
|-----------|-------|-------------------------------------------------------------------------|-------------|--------|
| AN0/DAN0+ | Input | Single-ended analog input / Differential analog input positive terminal | —           | Analog |
| AN1/DAN0- | Input | Single-ended analog input / Differential analog input negative terminal | —           | Analog |
| AN2/DAN1+ | Input | Single-ended analog input / Differential analog input positive terminal | —           | Analog |
| AN3/DAN1- | Input | Single-ended analog input / Differential analog input negative terminal | —           | Analog |
| AN4/DAN2+ | Input | Single-ended analog input / Differential analog input positive terminal | —           | Analog |
| AN5/DAN2- | Input | Single-ended analog input / Differential analog input negative terminal | —           | Analog |
| AN6/DAN3+ | Input | Single-ended analog input / Differential analog input positive terminal | —           | Analog |
| AN7/DAN3- | Input | Single-ended analog input / Differential analog input negative terminal | —           | Analog |

*Table continues on the next page...*

**Table 29-3. External signals (continued)**

| Name                  | Port   | Function                                                                         | Reset state | Type    |
|-----------------------|--------|----------------------------------------------------------------------------------|-------------|---------|
| AN8/ANW               | Input  | Single-ended analog input / Single-ended analog input from external multiplexers | —           | Analog  |
| AN9/ANX               | Input  | Single-ended analog input / Single-ended analog input from external multiplexers | —           | Analog  |

**Table 29-3. External signals (continued)**

| Name    | Port   | Function                            | Reset state | Type    |
|---------|--------|-------------------------------------|-------------|---------|
| MA2     | Output | External multiplexer control signal | 0           | Digital |
| VDDA    | Input  | Analog Positive Power Supply        | —           | Power   |
| VSSA    | Input  | Analog Negative Power Supply        | —           | Power   |
| VRH     | Input  | Voltage Reference High              | —           | Power   |
| VRL     | Input  | Voltage Reference Low               | —           | Power   |
| REFBYPC | Input  | External Bypass capacitor Pin       | —           | Power   |
| ETRIG0  | Input  | External trigger for CFIFO0         | —           | Digital |
| ETRIG1  | Input  | External trigger for CFIFO1         | —           | Digital |
| ETRIG2  | Input  | External trigger for CFIFO2         | —           | Digital |
| ETRIG3  | Input  | External trigger for CFIFO3         | —           | Digital |
| ETRIG4  | Input  | External trigger for CFIFO4         | —           | Digital |
| ETRIG5  | Input  | External trigger for CFIFO5         | —           | Digital |

1. Can be disabled or not using configuration parameters.

## 29.4.2 Detailed signal descriptions

### 29.4.2.1 AN0/DAN0+ — Single-ended analog input/Differential analog input positive terminal

AN0 is a single-ended analog input to the two on-chip ADCs. DAN0+ is the positive terminal of the differential analog input DAN0 (DAN0+ - DAN0-).

### 29.4.2.2 AN1/DAN0- — Single-ended analog input/Differential analog input negative terminal

AN1 is a single-ended analog input to the two on-chip ADCs. DAN0- is the negative terminal of the differential analog input DAN0 (DAN0+ - DAN0-).

### 29.4.2.3 AN2/DAN1+ — Single-ended analog input/Differential analog input positive terminal

AN2 is a single-ended analog input to the two on-chip ADCs. DAN1+ is the positive terminal of the differential analog input DAN1 (DAN1+ - DAN1-).

#### **29.4.2.4 AN3/DAN1- — Single-ended analog input/Differential analog input negative terminal**

AN3 is a single-ended analog input to the two on-chip ADCs. DAN1- is the negative terminal of the differential analog input DAN1 (DAN1+ - DAN1-).

#### **29.4.2.5 AN4/DAN2+ — Single-ended analog input/Differential analog input positive terminal**

AN4 is a single-ended analog input to the two on-chip ADCs. DAN2+ is the positive terminal of the differential analog input DAN2 (DAN2+ - DAN2-).

#### **29.4.2.6 AN5/DAN2- — Single-ended analog input/Differential analog input negative terminal**

AN5 is a single-ended analog input to the two on-chip ADCs. DAN2- is the negative terminal of the differential analog input DAN2 (DAN2+ - DAN2-).

#### **29.4.2.7 AN6/DAN3+ — Single-ended analog input/Differential analog input positive terminal**

AN6 is a single-ended analog input to the two on-chip ADCs. DAN3+ is the positive terminal of the differential analog input DAN3 (DAN3+ - DAN3-).

#### **29.4.2.8 AN7/DAN3- — Single-ended analog input/Differential analog input negative terminal**

AN7 is a single-ended analog input to the two on-chip ADCs. DAN3- is the negative terminal of the differential analog input DAN3 (DAN3+ - DAN3-).

#### **29.4.2.9 AN8/ANW — Single-ended analog input/ Single-ended analog input from external multiplexers**

AN8 is a single-ended analog input to the two on-chip ADCs. ANW is a single-ended analog input to one of the on-chip ADCs in external multiplexed mode.

#### **29.4.2.10 AN9/ANX/TBIAS — Single-ended analog input/ Single-ended analog input from external multiplexers/Test Bias**

AN9 is a single-ended analog input to the two on-chip ADCs. ANX is a single-ended analog input to one of the on-chip ADCs in external multiplexed mode. TBIAS is used during factory test to verify the bias generator circuit.

#### **29.4.2.11 AN10/ANY — Single-ended analog input/ Single-ended analog input from external multiplexers**

AN10 is a single-ended analog input to the two on-chip ADCs. ANY is a single-ended analog input to one of the on-chip ADCs in external multiplexed mode.

#### **29.4.2.12 AN11/ANZ — Single-ended analog input/ Single-ended analog input from external multiplexers**

AN11 is a single-ended analog input to the two on-chip ADCs. ANZ is a single-ended analog input to one of the on-chip ADCs in external multiplexed mode.

#### **29.4.2.13 AN12/T50PVREF — Single-ended analog input/ Test 50% VREF analog output**

AN12 is a single-ended analog input to the two on-chip ADCs. T50PVREF is used during ADC factory test.

#### **29.4.2.14 AN13/T25PVREF — Single-ended analog input/ Test 25% VREF analog output**

AN13 is a single-ended analog input to the two on-chip ADCs. T25PVREF is used during ADC factory test.

#### **29.4.2.15 AN14/T75PVREF — Single-ended analog input/ Test 75% VREF analog output**

AN14 is a single-ended analog input to the two on-chip ADCs. T75PVREF is used during ADC factory test.

#### **29.4.2.16 AN15 — Single-ended analog input**

AN15 is a single-ended analog inputs to the two on-chip ADCs.

#### **29.4.2.17 AN16/ANR — Single-ended analog input/ Single-ended analog input from external multiplexers**

AN16 is a single-ended analog input to the two on-chip ADCs. ANR is a single-ended analog input to one of the on-chip ADCs in external multiplexed mode. The external multiplexing capability is a device option.

#### **29.4.2.18 AN17/ANS — Single-ended analog input/ Single-ended analog input from external multiplexers**

AN17 is a single-ended analog input to the two on-chip ADCs. ANS is a single-ended analog input to one of the on-chip ADCs in external multiplexed mode. The external multiplexing capability is a device option.

#### **29.4.2.19 AN18/ANT — Single-ended analog input/ Single-ended analog input from external multiplexers**

AN18 is a single-ended analog input to the two on-chip ADCs. ANT is a single-ended analog input to one of the on-chip ADCs in external multiplexed mode. The external multiplexing capability is a device option.

#### **29.4.2.20 AN19/ANU — Single-ended analog input/ Single-ended analog input from external multiplexers**

AN19 is a single-ended analog input to the two on-chip ADCs. ANU is a single-ended analog input to one of the on-chip ADCs in external multiplexed mode. The external multiplexing capability is a device option.

#### **29.4.2.21 AN20-AN39 — Single-ended analog input**

AN20 through AN39 are single-ended analog inputs to the two on-chip ADCs.

**29.4.2.22 INA\_ADC0\_0 - INA\_ADC0\_9 — Single-ended analog input**

INA\_ADC0\_0 through INA\_ADC0\_9 are single-ended analog inputs to the on-chip ADC0.

**29.4.2.23 INA\_ADC1\_0 - INA\_ADC1\_9 — Single-ended analog input**

INA\_ADC1\_0 through INA\_ADC1\_9 are single-ended analog inputs to the on-chip ADC1.

**29.4.2.24 MA0-MA2 — External multiplexer control signals**

MA0, MA1, and MA2 combined form a select signal associated with external multiplexers.

**29.4.2.25 VRH, VRL — Voltage reference high and voltage reference low**

VRH and VRL are voltage references for the ADCs. VRH is the highest voltage reference, while VRL is the lowest voltage reference.

**29.4.2.26 VDDA, VSSA — 5V VDD and VSS for the 5V analog components**

VDDA is the positive power supply pin for the ADCs and VSSA is the negative power supply pin for the ADCs. Refer to electrical specifications.

**29.4.2.27 REFBYPC — Reference Bypass Capacitor**

The REFBYPC pin is used to connect an external bypass capacitor between REFBYPC and VRL. See section "Chip-specific EQADC information" for the capacitor value. This bypass capacitor is used to provide a stable reference voltage for the ADC.

**NOTE**

Prior EQADC versions have had two of these pins. To achieve accurate calibration, more time may be required with only one pin.

### 29.4.2.28 ETRIG0-ETRIG5 — External triggers

The external trigger signals are for hardware triggering. The EQADC can detect rising edge, falling edge, high level and low level on each of the external trigger signals. ETRIGx triggers CFIFOx. The EQADC also supports configurable digital filters for these external trigger signals. These digital filters can be bypassed by individual input control signals called eqadc\_intern\_trig\_selx.

## 29.5 Memory map and register definition

This section provides memory maps and detailed descriptions of all registers. Data written to or read from reserved areas of the memory map is undefined.

This section provides memory maps and detailed descriptions of all registers. Data written to or read from reserved areas of the memory map is undefined.

**EQADC memory map**

| Address offset (hex) | Register name                                                | Width (in bits) | Access | Reset value | Section/ page              |
|----------------------|--------------------------------------------------------------|-----------------|--------|-------------|----------------------------|
| 0                    | EQADC Module Configuration Register (EQADC_MCR)              | 32              | R/W    | 0000_0000h  | <a href="#">29.5.1/981</a> |
| 4                    | EQADC Test Register (EQADC_TST)                              | 32              | R      | 0000_0000h  | <a href="#">29.5.2/982</a> |

**29.5.1 EQADC Module Configuration Register (EQADC\_MCR)**

The EQADC Module Configuration Register (EQADC\_MCR) contains bits used to control how the EQADC responds to a debug mode entry request.

Address: 0h base + 0h offset = 0h

## 29.5.2 EQADC Test Register (EQADC\_TST)

The EQADC Test Register (EQADC\_TST) is used for test purposes only. This register can only be read/written in a test access, accessing the EQADC\_TST register in any other way will result in a transfer error. In a non-test access to the EQADC\_TST register, read data is undefined and written data is ignored.

### 29.5.3 EQADC External Trigger Digital Filter Register (EQADC\_ETDFR)

The EQADC External Trigger Digital Filter Register (EQADC\_ETDFR) is used to set the minimum time a signal must be held in a logic state on the CFIFO triggers inputs to be recognized as an edge or level gated trigger. The Digital Filter Length field specifies the minimum number of system clocks that must be counted by the digital filter counter to recognize a logic state change. However, there is a control signal that can be used to bypass the digital filter when this is not needed.

The count specifies the sample period of the digital filter which is calculated according to the following equation:

$$\text{FilterPeriod} = (\text{SystemClockPeriod} \times 2^{\text{DFL}}) + 1 (\text{SystemClockPeriod})$$

Minimum clock counts for which an ETRIG signal needs to be stable to be passed through the filter are shown in [Table 29-8](#). See [External trigger event detection](#) for more information on the digital filter.

#### NOTE

The DFL field must only be written when the MODEx of all CFIFOs are configured to disabled.

#### NOTE

When the digital filter is bypassed by using the input control, the DFL is not considered and the trigger input signal is not filtered.

**29.5.4 EQADC CFIFO Push Register (EQADC\_CFPRn)**

The EQADC CFIFO Push Registers (EQADC\_CFPR) provide a mechanism to fill the CFIFOs with command messages from the CQueues. Refer to [EQADC command FIFOs](#) for more information on the CFIFOs and to [Message format in EQADC](#) for a description on command message formats.

**NOTE**

Only whole words must be written to EQADC\_CFPR. Writing half-words or bytes to EQADC\_CFPR will still push the whole 32-bit CF\_PUSH field into the corresponding CFIFO, but undefined data will fill the areas of CF\_PUSH that were not specifically designated as target locations for the write.

Address: 0h base + 10h offset + (4d × i), where i=0d to 5d

| 16–31<br>RF_POPX | <p>Result FIFO Pop Data x</p> <p>When RFIFO<sub>x</sub> is not empty, the RF_POP<sub>x</sub> contains the next unread entry value of RFIFO<sub>x</sub>. Reading a word, a half-word, or any bytes from EQADC_RFPR<sub>x</sub> will pop one entry from RFIFO<sub>x</sub> and cause the RFCTR<sub>x</sub> field to be decremented by one in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISR<sub>n</sub>)</a> . When the RFIFO<sub>x</sub> is empty, any read on EQADC_RFPR<sub>x</sub> returns undefined data value and does not decrement the RFCTR<sub>x</sub> value. Writing to EQADC_RFPR<sub>x</sub> has no effect.</p> |

## 29.5.6 EQADC CFIFO Control Register 0 (EQADC\_CFCR0)

The EQADC CFIFO Control Registers (EQADC\_CFCR) contain bits that affect CFIFOs. These bits specify the CFIFO operation mode and can invalidate all of the CFIFO contents.

Address: 0h base + 50h offset = 50h

## EQADC\_CFCR0 field descriptions (continued)

| Field           | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
|-----------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                 | <p>The SSEx bit is used to set the SSSx bit in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISRn)</a> . Writing a "1" to SSEx will set the SSSx in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISRn)</a>, if the CFIFO is in single-scan mode. When SSSx is already asserted, writing a "1" to SSEx also has no effect. If the CFIFO is in continuous-scan mode or is disabled, writing a "1" to SSEx will not set SSSx. Writing a "0" to SSEx has no effect. SSEx always is read as "0".</p> <p>0 No effect.<br/>1 Set the SSSx bit.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |
| 6<br>CFINV0     | <p>CFIFO Invalidate Bit 0</p> <p>The CFINVx bit causes the EQADC to invalidate all entries of CFIFOx. Writing a "1" to CFINVx will reset the value of CFCTRx in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISRn)</a> . Writing a "1" to CFINVx also resets the Push Next Data Pointer, Transfer Next Data Pointer to the first entry of CFIFOx in <a href="#">Figure 29-123</a>. CFINVx always is read as "0". Writing a "0" has no effect.</p> <p><b>NOTE:</b> Writing CFINVx only invalidates commands stored in CFIFOx; previously transferred commands that are waiting for execution, that is commands stored in the CBuffers, will still be executed, and results generated by them will be stored in the appropriate RFIFO.</p> <p><b>NOTE:</b> CFINVx must not be written unless the MODEx is configured to disabled, and CFIFO status is IDLE.</p> <p>0 No effect.<br/>1 Invalidate all of the entries in the corresponding CFIFO.</p>                                                                                                                                                                                       |
| 7<br>Reserved   | <p>This field is reserved.<br/>This read-only field is reserved and always has the value 0.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| 8–11<br>MODE0   | <p>CFIFO Operation Mode 0</p> <p>The MODEx field selects the CFIFO operation mode for CFIFOx. See <a href="#">CFIFO scan trigger modes</a> for more information on CFIFO trigger mode.</p> <p><b>NOTE:</b> If MODEx is not disabled, it must not be changed to any other mode besides disabled. If MODEx is disabled and the CFIFO status is IDLE, MODEx can be changed to any other mode.</p> <p>0000 Disabled<br/>0001 Software Trigger, Single Scan<br/>0010 Low Level Gated External Trigger, Single Scan<br/>0011 High Level Gated External Trigger, Single Scan<br/>0100 Falling Edge External Trigger, Single Scan<br/>0101 Rising Edge External Trigger, Single Scan<br/>0110 Falling or Rising Edge External Trigger, Single Scan<br/>0111 Reserved<br/>1000 Reserved<br/>1001 Software Trigger, Continuous Scan<br/>1010 Low Level Gated External Trigger, Continuous Scan<br/>1011 High Level Gated External Trigger, Continuous Scan<br/>1100 Falling Edge External Trigger, Continuous Scan<br/>1101 Rising Edge External Trigger, Continuous Scan<br/>1110 Falling or Rising Edge External Trigger, Continuous Scan<br/>1111 Reserved</p> |
| 12–15<br>AMODE0 | <p>CFIFO0 Advance Trigger Operation Mode 0</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |

## 29.5.7 EQADC CFIFO Control Register 1 (EQADC\_CFCR1)

The EQADC CFIFO Control Registers (EQADC\_CFCR) contain bits that affect CFIFOs. These bits specify the CFIFO operation mode and can invalidate all of the CFIFO contents.

Address: 0h base + 54h offset = 54h

| 5<br>SSE2       | <p>CFIFO Single-Scan Enable Bit 2</p> <p>The SSE<sub>x</sub> bit is used to set the SSS<sub>x</sub> bit in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISR<sub>n</sub>)</a>. Writing a "1" to SSE<sub>x</sub> will set the SSS<sub>x</sub> in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISR<sub>n</sub>)</a>, if the CFIFO is in single-scan mode. When SSS<sub>x</sub> is already asserted, writing a "1" to SSE<sub>x</sub> also has no effect. If the CFIFO is in continuous-scan mode or is disabled, writing a "1" to SSE<sub>x</sub> will not set SSS<sub>x</sub>. Writing a "0" to SSE<sub>x</sub> has no effect. SSE<sub>x</sub> always is read as "0".</p> <p>0 No effect.<br/>1 Set the SSS<sub>x</sub> bit.</p>                                                                                                                                                                                                                                                   |
| 6<br>CFINV2     | <p>CFIFO Invalidate Bit 2</p> <p>The CFINV<sub>x</sub> bit causes the EQADC to invalidate all entries of CFIFO<sub>x</sub>. Writing a "1" to CFINV<sub>x</sub> will reset the value of CFCTR<sub>x</sub> in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISR<sub>n</sub>)</a>. Writing a "1" to CFINV<sub>x</sub> also resets the Push Next Data Pointer, Transfer Next Data Pointer to the first entry of CFIFO<sub>x</sub> in <a href="#">Figure 29-123</a>. CFINV<sub>x</sub> always is read as "0". Writing a "0" has no effect.</p> <p><b>NOTE:</b> Writing CFINV<sub>x</sub> only invalidates commands stored in CFIFO<sub>x</sub>; previously transferred commands that are waiting for execution, that is commands stored in the CBuffers, will still be executed, and results generated by them will be stored in the appropriate RFIFO.</p> <p><b>NOTE:</b> CFINV<sub>x</sub> must not be written unless the MODE<sub>x</sub> is configured to disabled, and CFIFO status is IDLE.</p> |

| 21<br>SSE3        | CFIFO Single-Scan Enable Bit 3<br>The SSEx bit is used to set the SSSx bit in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISRn)</a> . Writing a "1" to SSEx will set the SSSx in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISRn)</a> , if the CFIFO is in single-scan mode. When SSSx is already asserted, writing a "1" to SSEx also has no effect. If the CFIFO is in continuous-scan mode or is disabled, writing a "1" to SSEx will not set SSSx. Writing a "0" to SSEx has no effect. SSEx always is read as "0".<br><br>0 No effect.<br>1 Set the SSSx bit.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| 22<br>CFINV3      | CFIFO Invalidate Bit 3<br>The CFINVx bit causes the EQADC to invalidate all entries of CFIFOx. Writing a "1" to CFINVx will reset the value of CFCTRx in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISRn)</a> . Writing a "1" to CFINVx also resets the Push Next Data Pointer, Transfer Next Data Pointer to the first entry of CFIFOx in <a href="#">Figure 29-123</a> . CFINVx always is read as "0". Writing a "0" has no effect.<br><br><b>NOTE:</b> Writing CFINVx only invalidates commands stored in CFIFOx; previously transferred commands that are waiting for execution, that is commands stored in the CBuffers, will still be executed, and results generated by them will be stored in the appropriate RFIFO.<br><br><b>NOTE:</b> CFINVx must not be written unless the MODEx is configured to disabled, and CFIFO status is IDLE.                                                                                                                                                                                                                                                           |

## 29.5.8 EQADC CFIFO Control Register 2 (EQADC\_CFCR2)

The EQADC CFIFO Control Registers (EQADC\_CFCR) contain bits that affect CFIFOs. These bits specify the CFIFO operation mode and can invalidate all of the CFIFO contents.

Address: 0h base + 58h offset = 58h

| 5<br>SSE4       | CFIFO Single-Scan Enable Bit 4<br>The SSE <sub>x</sub> bit is used to set the SSS <sub>x</sub> bit in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISR<sub>n</sub>)</a> . Writing a "1" to SSE <sub>x</sub> will set the SSS <sub>x</sub> in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISR<sub>n</sub>)</a> , if the CFIFO is in single-scan mode. When SSS <sub>x</sub> is already asserted, writing a "1" to SSE <sub>x</sub> also has no effect. If the CFIFO is in continuous-scan mode or is disabled, writing a "1" to SSE <sub>x</sub> will not set SSS <sub>x</sub> . Writing a "0" to SSE <sub>x</sub> has no effect. SSE <sub>x</sub> always is read as "0".<br><br>0 No effect.<br>1 Set the SSS <sub>x</sub> bit.                                                                                                                                                                                                                                                     |
| 6<br>CFINV4     | CFIFO Invalidate Bit 4<br>The CFINV <sub>x</sub> bit causes the EQADC to invalidate all entries of CFIFO <sub>x</sub> . Writing a "1" to CFINV <sub>x</sub> will reset the value of CFCTR <sub>x</sub> in <a href="#">EQADC FIFO and Interrupt Status Register (EQADC_FISR<sub>n</sub>)</a> . Writing a "1" to CFINV <sub>x</sub> also resets the Push Next Data Pointer, Transfer Next Data Pointer to the first entry of CFIFO <sub>x</sub> in <a href="#">Figure 29-123</a> . CFINV <sub>x</sub> always is read as "0". Writing a "0" has no effect.<br><br><b>NOTE:</b> Writing CFINV <sub>x</sub> only invalidates commands stored in CFIFO <sub>x</sub> ; previously transferred commands that are waiting for execution, that is commands stored in the CBuffers, will still be executed, and results generated by them will be stored in the appropriate RFIFO.<br><br><b>NOTE:</b> CFINV <sub>x</sub> must not be written unless the MODE <sub>x</sub> is configured to disabled, and CFIFO status is IDLE. |

## 29.5.9 EQADC Interrupt and DMA Control Register 0 (EQADC\_IDCR0)

The EQADC Interrupt Control Registers (EQADC\_IDCR) contain bits to enable the generation of interrupt or DMA requests when the corresponding flag bits are set in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#).

Address: 0h base + 60h offset = 60h

## 29.5.10 EQADC Interrupt and DMA Control Register 1 (EQADC\_IDCR1)

The EQADC Interrupt Control Registers (EQADC\_IDCR) contain bits to enable the generation of interrupt or DMA requests when the corresponding flag bits are set in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#).

Address: 0h base + 64h offset = 64h

### 29.5.11 EQADC Interrupt and DMA Control Register 2 (EQADC\_IDCR2)

The EQADC Interrupt Control Registers (EQADC\_IDCR) contain bits to enable the generation of interrupt or DMA requests when the corresponding flag bits are set in [EQADC FIFO and Interrupt Status Register \(EQADC\\_FISR<sub>n</sub>\)](#).

Address: 0h base + 68h offset = 68h

29.5.12 EQADC FIFO and Interrupt Status Register (EQADC\_FISRn)

The EQADC FIFO and Interrupt Status Registers (EQADC\_FISR) contain flag and status bits for each CFIFO and RFIFO pair. Write "1" to a flag bit to clear it. Writing "0" has no effect. Status bits are read only. These bits indicate the status of the FIFO itself.

Address: 0h base + 70h offset + (4d × i), where i=0d to 5d

|------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 1<br>TORFX | <p>Trigger Overrun Flag for CFIFO<sub>x</sub></p> <p>TORFX is set when trigger overrun occurs for the specified CFIFO in edge or level trigger mode. Trigger overrun occurs when an already triggered CFIFO receives an additional trigger. When TORIE<sub>x</sub> in <a href="#">EQADC Interrupt and DMA Control Register 0 (EQADC_IDCR0)</a> and TORFX are asserted, an interrupt request will be generated.</p> <p>Apart from generating an independent interrupt request for a CFIFO<sub>x</sub> Trigger Overrun event, the EQADC also provides a combined interrupt at which the Result FIFO Overflow Interrupt, the Command FIFO Underflow Interrupt, and the Command FIFO Trigger Overrun Interrupt requests of ALL CFIFOs are ORed. When RFOIE<sub>x</sub>, CFUIE<sub>x</sub>, and TORIE<sub>x</sub> are all asserted, this combined interrupt request is asserted whenever one of the following 18 flags becomes asserted: RFOFX, CFUFx, and TORFX (assuming that all interrupts are enabled). See <a href="#">EQADC DMA/interrupt request</a> for details.</p> <p>Write "1" to clear the TORFX bit. Writing a "0" has no effect.</p> <p><b>NOTE:</b> The trigger overrun flag will not set for CFIFOs configured for software trigger mode.</p> <p>0 No trigger overrun occurred.<br/>1 Trigger overrun occurred.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| 2<br>PFX   | <p>Pause Flag x</p> <p>PF behavior changes according to the CFIFO trigger mode. In edge trigger mode, PFX is set when the EQADC completes the transfer of an entry with an asserted Pause bit from CFIFO<sub>x</sub>. In level trigger mode, when CFIFO<sub>x</sub> is in TRIGGERED status, PFX is set when CFIFO status changes from TRIGGERED due to the detection of a closed gate. An interrupt routine, generated due to the asserted PF, can be used to verify if a complete scan of the CQueue was performed. If a closed gate is detected while no command transfers are taking place, it will have immediate effect on the CFIFO status. If a closed gate is detected while a command transfer to an on-chip CBuffer is taking place, it will only affect the CFIFO status when the transfer completes. The transfer of entries bound for the on-chip ADCs is considered completed when they are stored in the appropriate CBuffer. In software trigger mode, PFX will never become asserted.</p> <p>If PIE<sub>x</sub> in <a href="#">EQADC Interrupt and DMA Control Register 0 (EQADC_IDCR0)</a> and PFX are asserted, an interrupt will be generated. Write "1" to clear the PFX. Writing a "0" has no effect. See <a href="#">Pause status</a> for more information on the Pause Flag.</p> <p><b>NOTE:</b> In edge trigger mode, an asserted PFX only implies that the EQADC has finished transferring a command with an asserted PAUSE bit from CFIFO<sub>x</sub>. It does not imply that result data for the current command and for all previously transferred commands has been returned to the appropriate RFIFO.</p> <p><b>NOTE:</b> In software or level trigger mode, when the EQADC completes the transfer of an entry from CFIFO<sub>x</sub> with an asserted PAUSE bit, PFX will not be set and transfer of commands will continue without pausing.</p> <p>0 Entry with asserted PAUSE bit was not transferred from CFIFO<sub>x</sub> (CFIFO in edge trigger mode), or CFIFO status did not change from TRIGGERED due to detection of a closed gate (CFIFO in level trigger mode).<br/>1 Entry with asserted PAUSE bit was transferred from CFIFO<sub>x</sub> (CFIFO in edge trigger mode), or CFIFO status changes from TRIGGERED due to detection of a closed gate (CFIFO in level trigger mode).</p> |
| 3<br>EOQFX | <p>End of Queue Flag x</p> <p>EOQFX indicates that an entry with an asserted EOQ bit was transferred from CFIFO<sub>x</sub> to the on-chip ADCs - see <a href="#">Message format in EQADC</a> for details about command message formats. When the EQADC completes the transfer of an entry with an asserted EOQ bit from CFIFO<sub>x</sub>, EOQFX will be set. The transfer of entries bound for the on-chip ADCs is considered completed when they are stored in the appropriate</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |

| Field                  | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                          |
|------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|                        | <p>CBuffer. If the EOQIE<sub>x</sub> bit in <a href="#">EQADC Interrupt and DMA Control Register 0 (EQADC_IDCR0)</a> and EOQF<sub>x</sub> are asserted, an interrupt will be generated. Write "1" to clear the EOQF<sub>x</sub> bit. Writing a "0" has no effect. Refer to <a href="#">CQueue completion status</a> for more information on the End of Queue Flag.</p> <p><b>NOTE:</b> An asserted EOQF<sub>x</sub> only implies that the EQADC has finished transferring a command with an asserted EOQ bit from CFIFO<sub>x</sub>. It does not imply that result data for the current command and for all previously transferred commands has been returned to the appropriate RFIFO.</p> <p>0 Entry with asserted EOQ bit was not transferred from CFIFO<sub>x</sub>.<br/>1 Entry with asserted EOQ bit was transferred from CFIFO<sub>x</sub>.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                               |
| 4<br>CFUF <sub>x</sub> | <p>CFIFO Underflow Flag x</p> <p>CFUF<sub>x</sub> indicates an underflow event on CFIFO<sub>x</sub>. CFUF<sub>x</sub> is set when CFIFO<sub>x</sub> is in TRIGGERED state and it becomes empty. No commands will be transferred from an underflowing CFIFO, nor will command transfers from lower priority CFIFOs be blocked. When CFUIE<sub>x</sub> in <a href="#">EQADC Interrupt and DMA Control Register 0 (EQADC_IDCR0)</a> and CFUF<sub>x</sub> are both asserted, the EQADC generates an interrupt request.</p> <p>Apart from generating an independent interrupt request for a CFIFO<sub>x</sub> underflow event, the EQADC also provides a combined interrupt at which the Result FIFO Overflow Interrupt, the Command FIFO Underflow Interrupt, and the Command FIFO Trigger Overrun Interrupt requests of ALL CFIFOs are ORed. When RFOIE<sub>x</sub>, CFUIE<sub>x</sub>, and TORIE<sub>x</sub> are all asserted, this combined interrupt request is asserted whenever one of the following 18 flags becomes asserted: RFOF<sub>x</sub>, CFUF<sub>x</sub>, and TORF<sub>x</sub> (assuming that all interrupts are enabled). See <a href="#">EQADC DMA/interrupt request</a> for details.</p> <p>Write "1" to clear CFUF<sub>x</sub>. Writing a "0" has no effect.</p> <p>0 No CFIFO underflow event occurred.<br/>1 A CFIFO underflow event occurred.</p> |
| 5<br>SSS <sub>x</sub>  | <p>CFIFO Single-Scan Status Bit x</p> <p>An asserted SSS<sub>x</sub> bit enables the detection of trigger events for CFIFOs programmed into single-scan level- or edge-trigger mode, and works as trigger for CFIFOs programmed into single-scan software-trigger mode. See <a href="#">Single-scan mode</a> for further details. The SSS<sub>x</sub> bit is set by writing a "1" to the SSE<sub>x</sub> bit in <a href="#">EQADC CFIFO Control Register 0 (EQADC_CFCR0)</a>. The EQADC clears the SSS<sub>x</sub> bit when a command with an asserted EOQ bit is transferred from a CFIFO in single-scan mode, when a CFIFO is in single-scan level-trigger mode and its status changes from TRIGGERED due to the detection of a closed gate, or when the value of the CFIFO operation mode (MODE<sub>x</sub>) in <a href="#">EQADC CFIFO Control Register 0 (EQADC_CFCR0)</a> is changed to disabled. Writing to SSS<sub>x</sub> has no effect. SSS<sub>x</sub> has no effect in continuous-scan or in disabled mode.</p> <p>0 CFIFO in single-scan level- or edge-trigger mode will ignore trigger events, or CFIFO in single-scan software-trigger mode is not triggered.<br/>1 CFIFO in single-scan level- or edge-trigger mode will detect a trigger event, or CFIFO in single-scan software-trigger mode is triggered.</p>                                    |
| 6<br>CFFF <sub>x</sub> | <p>CFIFO Fill Flag x</p> <p>CFFF<sub>x</sub> is set when the CFIFO<sub>x</sub> is not full. When CFFE<sub>x</sub> in <a href="#">EQADC Interrupt and DMA Control Register 0 (EQADC_IDCR0)</a> and CFFF<sub>x</sub> are both asserted, an interrupt or a DMA request will be generated depending on the status of the CFFS<sub>x</sub> bit. When CFFS<sub>x</sub> is negated (interrupt requests selected), software clears CFFF<sub>x</sub> by writing a "1" to it. Writing a "0" has no effect. When CFFS<sub>x</sub> is asserted (DMA requests selected), CFFF<sub>x</sub> is automatically cleared by the EQADC when the CFIFO becomes full.</p> <p><b>NOTE:</b> Writing "1" to CFFF<sub>x</sub> when CFFS<sub>x</sub> is asserted (DMA requests selected) is not allowed.</p> <p><b>NOTE:</b> When generation of interrupt requests is selected (CFFS<sub>x</sub>=0), CFFF<sub>x</sub> must only be cleared in the ISR after the CFIFO<sub>x</sub> push register is accessed.</p>                                                                                                                                                                                                                                                                                                                                                                                |

|                   | 0 CFIFO <sub>x</sub> is full.<br>1 CFIFO <sub>x</sub> is not full.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| 7–11<br>Reserved  | This field is reserved.<br>This read-only field is reserved and always has the value 0.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| 12<br>RFOFX       | RFIFO Overflow Flag x<br><p>RFOFX indicates an overflow event on RFIFO<sub>x</sub>. RFOFX is set when RFIFO<sub>x</sub> is already full, and a new data is received from the on-chip ADCs. The RFIFO<sub>x</sub> will not overwrite older data in the RFIFO, and the new data will be ignored. When RFOIEx in <a href="#">EQADC Interrupt and DMA Control Register 0 (EQADC_IDCR0)</a> and RFOFX are both asserted, the EQADC generates an interrupt request.</p> <p>Apart from generating an independent interrupt request for an RFIFO<sub>x</sub> overflow event, the EQADC also provides a combined interrupt at which the Result FIFO Overflow Interrupt, the Command FIFO Underflow Interrupt, and the Command FIFO Trigger Overrun Interrupt requests of ALL CFIFOs are ORed. When RFOIEx, CFUIEx, and TORIEx are all asserted, this combined interrupt request is asserted whenever one of the following 18 flags becomes asserted: RFOFX, CFUFx, and TORFx (assuming that all interrupts are enabled). See <a href="#">EQADC DMA/interrupt request</a> for details.</p> <p>Write "1" to clear RFOFX. Writing a "0" has no effect.</p> 0 No RFIFO overflow event occurred.<br>1 An RFIFO overflow event occurred. |

| 24–27<br>RFCTR <sub>x</sub>     | <p>RFIFO<sub>x</sub> Entry Counter</p> <p>RFCTR<sub>x</sub> indicates the number of data items stored in the RFIFO<sub>x</sub>. When the EQADC stores a piece of new data into RFIFO<sub>x</sub>, it increments RFCTR<sub>x</sub> by one. Reading the whole word, half-word or any bytes of the corresponding <a href="#">EQADC Result FIFO Pop Register (EQADC_RFPR<sub>n</sub>)</a> decrements RFCTR<sub>x</sub> by one. Writing any value to RFCTR<sub>x</sub> itself has no effect.</p> <p><b>NOTE:</b> When the DMA request is selected ((RFDS<sub>x</sub>=1), the decrement of RFCTR<sub>x</sub> should be done only readings controlled by the DMA external block. Flushing of the RFIFO<sub>x</sub> decrements the RFCTR<sub>x</sub> to zero and can lead the DMA system to a locked state (DMA request ON).</p> |
| 28–31<br>POPNXTPTR <sub>x</sub> | <p>RFIFO<sub>x</sub> Pop Next Pointer</p> <p>POPNXTPTR<sub>x</sub> indicates the index of the entry that will be returned when EQADC_RFPR<sub>x</sub> is read. When POPNXTPTR<sub>x</sub> is zero, it points to the entry with the smallest memory-mapped address inside RFIFO<sub>x</sub>. POPNXTPTR<sub>x</sub> is updated when EQADC_RFPR<sub>x</sub> is read. If the maximum index number (RFIFO depth minus one) is reached, POPNXTPTR<sub>x</sub> is wrapped to zero, else, it is incremented by one. For details refer to <a href="#">RFIFO basic functionality</a>. Writing any value to POPNXTPTR<sub>x</sub> has no effect.</p>                                                                                                                                                                                |

### 29.5.13 EQADC CFIFO Transfer Counter Register 0 (EQADC\_CFTCR0)

The EQADC CFIFO Transfer Counter Registers (EQADC\_CFTCR) record the number of commands transferred from a CFIFO. The EQADC\_CFTCR supports the monitoring of command transfers from a CFIFO.

Address: 0h base + 90h offset = 90h

## 29.5.15 EQADC CFIFO Transfer Counter Register 2 (EQADC\_CFTCR2)

The EQADC CFIFO Transfer Counter Registers (EQADC\_CFTCR) record the number of commands transferred from a CFIFO. The EQADC\_CFTCR supports the monitoring of command transfers from a CFIFO.

**29.5.16 EQADC CFIFO Status Snapshot Register 0 (EQADC\_CFSSR0)**

The EQADC CFIFO Status Snapshot Registers (EQADC\_CFSSR) contain status fields to track the operation status of each CFIFO and the transfer counter of the last CFIFO to initiate a command transfer to the internal CBuffers. EQADC\_CFSSR0-1 are related to the on-chip CBuffers (CBuffer0-1). All fields of a particular EQADC\_CFSSR register are captured at the beginning of a command transfer to the CBuffer associated with that register. Note that captured status register values are associated with previous command transfer. This means that the CFSSR registers capture the status registers before the status registers change because of the transfer of the current command that is about to be popped from the CFIFO. The EQADC\_CFSSR registers are read only. Writing to the EQADC\_CFSSR registers has no effect.
